The current in a circuit due to a changing magnetic field is called an **induced current.** Opening the switch or moving the magnet *induces* a current in a nearby circuit. An induced current is not caused by a battery. It is a completely new way to generate a current, and we will have to discover how it is similar to and how it is different from currents we have studied previously.

Magnetic data storage, whether it's the magnetic stripe on a credit card or a 20 GB hard disk, encodes information in a pattern of alternating magnetic fields. When these fields move past a small *pick-up coil*, the changing magnetic field creates an induced current in the coil. This current is amplified into a sequence of voltage pulses that represent the 0s and 1s of digital data. Magnetic data storage is just one of countless applications of electromagnetic induction.

34.2 Motional emf

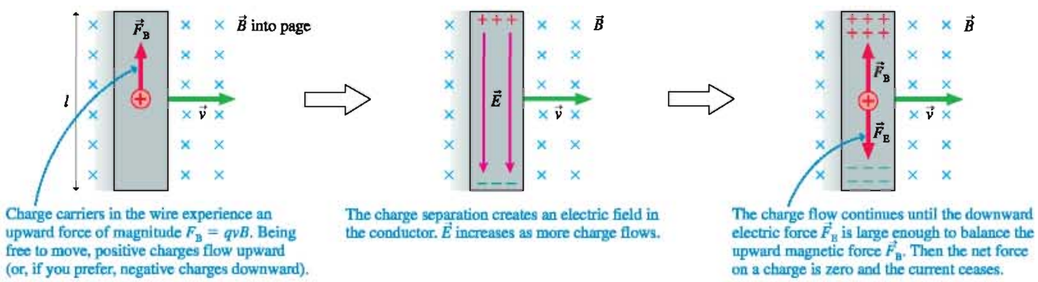
An induced current can be created two different ways:

1. By changing the size or orientation of a circuit in a stationary magnetic field, or
2. By changing the magnetic field through a stationary circuit.

Although the effects are the same, the causes turn out to be different. We'll start our investigation of electromagnetic induction by looking at situations in which the magnetic field is fixed while the circuit moves or changes.

To begin, consider a conductor of length l that moves with velocity $\vec{v}$ through a uniform magnetic field $\vec{B}$, as shown in FIGURE 34.2. The charge carriers inside the wire also move with velocity $\vec{v}$, so they each experience a magnetic force $\vec{F}_B = q\vec{v} \times \vec{B}$. For simplicity, we will assume that $\vec{v}$ is perpendicular to $\vec{B}$, in which case the strength of the force is $F_B = qvB$. This force causes the charge carriers to move, separating the positive and negative charges. The separated charges then create an electric field inside the conductor.

FIGURE 34.2 The magnetic force on the charge carriers in a moving conductor creates an electric field inside the conductor.



The charge carriers continue to move until the electric force $F_E = qE$ exactly balances the magnetic force $F_B = qvB$. This balance happens when the electric field strength is

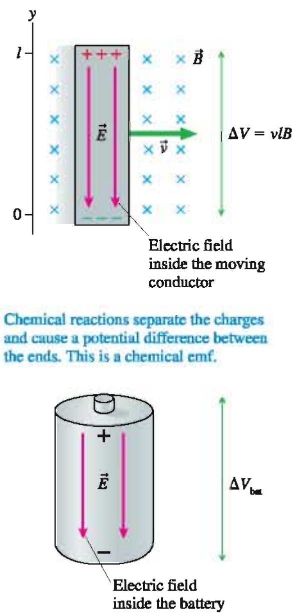
$$E = vB \tag{34.1}$$

In other words, **the magnetic force on the charge carriers in a moving conductor creates an electric field $E = vB$ inside the conductor.**

FIGURE 34.3 Two different ways to generate an emf.

(a) Magnetic forces separate the charges and cause a potential difference between the ends. This is a motional emf.

(b) Chemical reactions separate the charges and cause a potential difference between the ends. This is a chemical emf.



The electric field, in turn, creates an electric potential difference between the two ends of the moving conductor. **FIGURE 34.3a** defines a coordinate system in which $\vec{E} = -vB\hat{j}$. Using the connection between the electric field and the electric potential that we found in Chapter 30,

$$\Delta V = V_{top} - V_{bottom} = -\int_0^l E_y\,dy = -\int_0^l (-vB)\,dy = vlB \qquad (34.2)$$

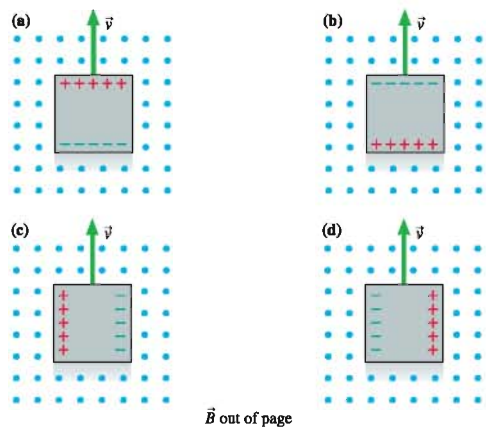
Thus the motion of the wire through a magnetic field *induces* a potential difference vlB between the ends of the conductor. The potential difference depends on the strength of the magnetic field and on the wire's speed through the field.

There's an important analogy between this potential difference and the potential difference of a battery. **FIGURE 34.3b** reminds you that a battery uses a nonelectric force—the charge escalator—to separate positive and negative charges. The emf $\mathcal{E}$ of the battery was defined as the work performed per charge (W/q) to separate the charges. An isolated battery, with no current, has a potential difference $\Delta V_{bat} = \mathcal{E}$. We could refer to a battery, where the charges are separated by chemical reactions, as a source of *chemical emf*.

The moving conductor develops a potential difference because of the work done by magnetic forces to separate the charges. You can think of the moving conductor as a "battery" that stays charged only as long as it keeps moving but "runs down" if it stops. The emf of the conductor is due to its motion, rather than to chemical reactions inside, so we can define the **motional emf** of a conductor moving with velocity $\vec{v}$ perpendicular to a magnetic field $\vec{B}$ to be

$$\mathcal{E} = vlB \qquad (34.3)$$

STOP TO THINK 34.1 A square conductor moves through a uniform magnetic field. Which of the figures shows the correct charge distribution on the conductor?



EXAMPLE 34.1 Measuring the earth's magnetic field

It is known that the earth's magnetic field over northern Canada points straight down. The crew of a Boeing 747 aircraft flying at 260 m/s over northern Canada finds a 0.95 V potential difference between the wing tips. The wing span of a Boeing 747 is 65 m. What is the magnetic field strength there?

MODEL The wing is a conductor moving through a magnetic field, so there is a motional emf.

SOLVE The magnetic field is perpendicular to the velocity, so we can use Equation 34.3 to find

$$B = \frac{\mathcal{E}}{vL} = \frac{0.95\text{ V}}{(260\text{ m/s})(65\text{ m})} = 5.6 \times 10^{-5}\text{ T}$$

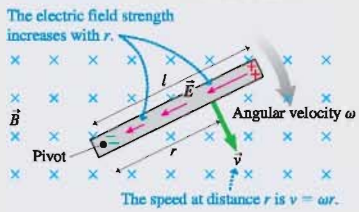
ASSESS Chapter 33 noted that the earth's magnetic field is roughly 5×10^{-5} T. The field is somewhat stronger than this near the magnetic poles, somewhat weaker near the equator.

EXAMPLE 34.2 Potential difference along a rotating bar

A metal bar of length l rotates with angular velocity ω about a pivot at one end of the bar. A uniform magnetic field $\vec{B}$ is perpendicular to the plane of rotation. What is the potential difference between the ends of the bar?

VISUALIZE FIGURE 34.4 is a pictorial representation of the bar. The magnetic forces on the charge carriers will cause the outer end to be positive with respect to the pivot.

FIGURE 34.4 Pictorial representation of a metal bar rotating in a magnetic field.



SOLVE Even though the bar is rotating, rather than moving in a straight line, the velocity of each charge carrier is perpendicular to $\vec{B}$. Consequently, the electric field created inside the bar is exactly that given in Equation 34.1, $E = vB$. But v, the speed of the charge carrier, now depends on its distance from the pivot. Recall that in rotational motion the tangential speed at radius r from the center of rotation is $v = \omega r$. Thus the electric field at distance r from the pivot is $E = \omega r B$. The electric field increases in strength as you move outward along the bar.

The electric field $\vec{E}$ points toward the pivot, so its radial component is $E_r = -\omega r B$. If we integrate outward from the center, the potential difference between the ends of the bar is

$$\Delta V = V_{\text{tip}} - V_{\text{pivot}} = -\int_0^l E_r\, dr$$

$$= -\int_0^l (-\omega r B)\, dr = \omega B \int_0^l r\, dr = \frac{1}{2}\omega l^2 B$$

ASSESS $\frac{1}{2}\omega l$ is the speed at the midpoint of the bar. Thus ΔV is $v_{\text{mid}} l B$, which seems reasonable.

Induced Current in a Circuit

The moving conductor of Figure 34.2 had an emf, but it couldn't sustain a current because the charges had nowhere to go. It's like a battery that is disconnected from a circuit. We can change this by including the moving conductor in a circuit.

FIGURE 34.5 shows a conducting wire sliding with speed v along a U-shaped conducting rail. We'll assume that the rail is attached to a table and cannot move. The wire and the rail together form a closed conducting loop—a circuit.

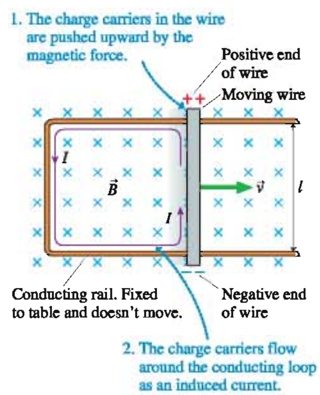
Suppose a magnetic field $\vec{B}$ is perpendicular to the plane of the circuit. Charges in the moving wire will be pushed to the ends of the wire by the magnetic force, just as they were in Figure 34.2, but now the charges can continue to flow around the circuit. That is, the moving wire acts like a battery in a circuit.

The current in the circuit is an *induced current*. In this example, the induced current is counterclockwise (ccw). If the total resistance of the circuit is R, the induced current is given by Ohm's law as

$$I = \frac{\mathcal{E}}{R} = \frac{vlB}{R} \tag{34.4}$$

In this situation, the induced current is due to magnetic forces on moving charges.

FIGURE 34.5 A current is induced in the circuit as the wire moves through a magnetic field.



STOP TO THINK 34.2 Is there an induced current in this circuit? If so, what is its direction?

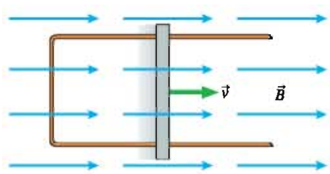


FIGURE 34.6 A pulling force is needed to move the wire to the right.

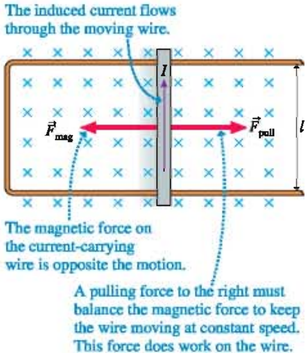


We've assumed that the wire is moving along the rail at constant speed. It turns out that we must apply a continuous pulling force $\vec{F}_{pull}$ to make this happen. **FIGURE 34.6** shows why. The moving wire, which now carries induced current I, is in a magnetic field. You learned in Chapter 33 that a magnetic field exerts a force on a current-carrying wire. According to the right-hand rule, the magnetic force $\vec{F}_{mag}$ on the moving wire points to the left. This "magnetic drag" will cause the wire to slow down and stop *unless* we exert an equal but opposite pulling force $\vec{F}_{pull}$ to keep the wire moving.

NOTE ▶ Think about this carefully. As the wire moves to the right, the magnetic force $\vec{F}_B$ pushes the charge carriers *parallel* to the wire. Their motion, as they continue around the circuit, is the induced current I. Now, because we have a current, a second magnetic force $\vec{F}_{mag}$ enters the picture. This force on the current is *perpendicular* to the wire and acts to slow the wire's motion. ◀

The magnitude of the magnetic force on a current-carrying wire was found in Chapter 33 to be $F_{mag} = IlB$. Using that result, along with Equation 34.4 for the induced current, we find that the force required to pull the wire with a constant speed v is

$$F_{pull} = F_{mag} = IlB = \left(\frac{vlB}{R}\right)lB = \frac{vl^2B^2}{R} \tag{34.5}$$

Energy Considerations

The environment must do work on the wire to pull it. What happens to the energy transferred to the wire by this work? Is energy conserved as the wire moves along the rail? It will be easier to answer this question if we think about power rather than work. Power is the *rate* at which work is done on the wire. You learned in Chapter 11 that the power exerted by a force pushing or pulling an object with velocity v is $P = Fv$. The power provided to the circuit by pulling on the wire is

$$P_{input} = F_{pull}v = \frac{v^2l^2B^2}{R} \tag{34.6}$$

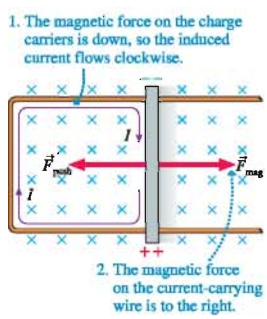
This is the rate at which energy is added to the circuit by the pulling force.

But the circuit also dissipates energy by transforming electric energy into the thermal energy of the wires and components, heating them up. As we found in Chapter 32, the power dissipated by current I as it passes through resistance R is $P = I^2R$. Equation 34.4 for the induced current I gives us the power dissipated by the circuit of Figure 34.5:

$$P_{dissipated} = I^2R = \frac{v^2l^2B^2}{R} \tag{34.7}$$

You can see that Equations 34.6 and 34.7 are identical. **The rate at which work is done on the circuit exactly balances the rate at which energy is dissipated.** Thus *energy is conserved.*

FIGURE 34.7 A pushing force is needed to move the wire to the left.



If you have to *pull* on the wire to get it to move to the right, you might think that it would spring back to the left on its own. **FIGURE 34.7** shows the same circuit with the wire moving to the left. In this case, you must *push* the wire to the left to keep it moving. The magnetic force is always opposite to the wire's direction of motion.

In both Figure 34.6, where the wire is pulled, and Figure 34.7, where it is pushed, a mechanical force is used to create a current. In other words, we have a conversion of *mechanical* energy to *electric* energy. A device that converts mechanical energy to electric energy is called a **generator.** The slide-wire circuits of Figure 34.6 and 34.7 are simple examples of a generator. We will look at more practical examples of generators later in the chapter.

We can summarize our analysis as follows:

1. Pulling or pushing the wire through the magnetic field at speed v creates a motional emf $\mathcal{E}$ in the wire and induces a current $I = \mathcal{E}/R$ in the circuit.

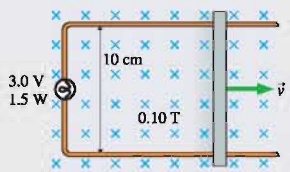
2. To keep the wire moving at constant speed, a pulling or pushing force must balance the magnetic force on the wire. This force does work on the circuit.
3. The work done by the pulling or pushing force exactly balances the energy dissipated by the current as it passes through the resistance of the circuit.

EXAMPLE 34.3 Lighting a bulb

FIGURE 34.8 shows a circuit consisting of a flashlight bulb, rated 3.0 V/1.5 W, and ideal wires with no resistance. The right wire of the circuit, which is 10 cm long, is pulled at constant speed v through a perpendicular magnetic field of strength 0.10 T.

a. What speed must the wire have to light the bulb to full brightness?
b. What force is needed to keep the wire moving?

FIGURE 34.8 Circuit of Example 34.3.



MODEL Treat the moving wire as a source of motional emf.

VISUALIZE The direction of the magnetic force on the charge carriers, $\vec{F}_B = q\vec{v} \times \vec{B}$, will cause a counterclockwise (ccw) induced current.

SOLVE a. The bulb's rating of 3.0 V/1.5 W means that at full brightness it will dissipate 1.5 W at a potential difference of 3.0 V. Because the power is related to the voltage and current by $P = I\Delta V$, the current causing full brightness is

$$I = \frac{P}{\Delta V} = \frac{1.5\text{ W}}{3.0\text{ V}} = 0.50\text{ A}$$

The bulb's resistance—the total resistance of the circuit—is

$$R = \frac{\Delta V}{I} = \frac{3.0\text{ V}}{0.50\text{ A}} = 6.0\ \Omega$$

Equation 34.4 gives the speed needed to induce this current:

$$v = \frac{IR}{lB} = \frac{(0.50\text{ A})(6.0\ \Omega)}{(0.10\text{ m})(0.10\text{ T})} = 300\text{ m/s}$$

You can confirm from Equation 34.6 that the input power at this speed is 1.5 W.

b. From Equation 34.5, the pulling force must be

$$F_{\text{pull}} = \frac{vl^2B^2}{R} = 5.0 \times 10^{-3}\text{ N}$$

You can also obtain this result from $F_{\text{pull}} = P/v$.

ASSESS Example 34.1 showed that high speeds are needed to produce significant potential difference. Thus 300 m/s is not surprising. The pulling force is not very large, but even a small force can deliver large amounts of power $P = Fv$ when v is large.

Eddy Currents

FIGURE 34.9 shows a *rigid* square loop of wire between the poles of a magnet. The magnetic field points downward and is confined to the region between the poles. The magnetic field in Figure 34.9a passes through the loop, but the wires are not in the field. None of the charge carriers in the wire experience a magnetic force, so there is no induced current and it takes no force to pull the loop to the right.

But when the left edge of the loop enters the field, as shown in Figure 34.9b, the magnetic force on the charge carriers induces a current in the loop. The magnetic field then exerts a retarding magnetic force on this current, so **a pulling force must be exerted to pull the loop out of the magnetic field.** Note that the wire, typically copper, is *not* a magnetic material. A piece of the wire held near the magnet would feel no force. Nor would a force be required to pull the wire out if there were a gap in the loop, breaking the circuit and preventing a current. It is the *induced current* in the complete loop that causes the wire to experience a retarding force.

These ideas have interesting implications. Consider pulling a *sheet* of metal through a magnetic field, as shown in FIGURE 34.10a on the next page. The metal, we will assume, is not a magnetic material, so it experiences no magnetic force if it is at rest. The charge carriers in the metal experience a magnetic force as the sheet is dragged between the pole tips of the magnet. A current is induced, just as in the loop of wire, but here the currents do not have wires to define their path. As a consequence, two "whirlpools" of current begin to circulate in the metal. These spread-out current whirlpools in a solid metal are called **eddy currents.**

FIGURE 34.9 Pulling a loop of wire out of a magnetic field.

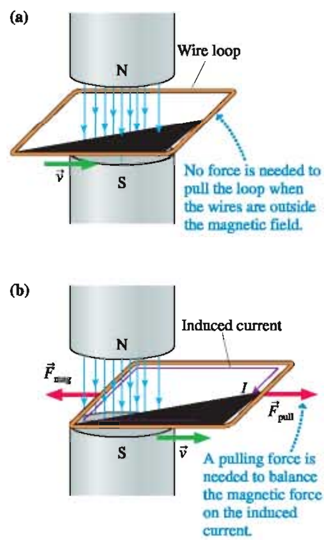


FIGURE 34.10 Eddy currents.

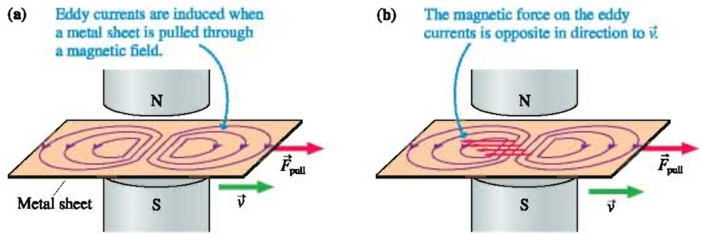

FIGURE 34.10b shows the magnetic force on the eddy current as it passes between the pole tips. This force is to the left, acting as a retarding force. Thus **an external force is required to pull a metal through a magnetic field.** If the pulling force ceases, the retarding magnetic force quickly causes the metal to decelerate until it stops. Similarly, a force is required to push a sheet of metal *into* a magnetic field.

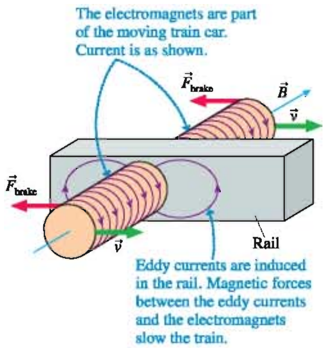
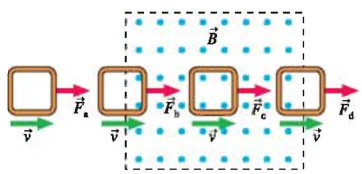
FIGURE 34.11 Magnetic braking systems are an application of eddy currents.



Eddy currents are often undesirable. The power dissipation of eddy currents can cause unwanted heating, and the magnetic forces on eddy currents mean that extra energy must be expended to move metals in magnetic fields. But eddy currents also have important useful applications. A good example is magnetic braking, which is used in some trains and transit-system vehicles.

The moving train car has an electromagnet that straddles the rail, as shown in FIGURE 34.11. During normal travel, there is no current through the electromagnet and no magnetic field. To stop the car, a current is switched into the electromagnet. The current creates a strong magnetic field that passes *through* the rail, and the motion of the rail relative to the magnet induces eddy currents in the rail. The magnetic force between the electromagnet and the eddy currents acts as a braking force on the magnet and, thus, on the car. Magnetic braking systems are very efficient, and they have the added advantage that they heat the rail rather than the brakes.

STOP TO THINK 34.3 A square loop of copper wire is pulled through a region of magnetic field. Rank in order, from strongest to weakest, the pulling forces $\vec{F}_a$, $\vec{F}_b$, $\vec{F}_c$, and $\vec{F}_d$ that must be applied to keep the loop moving at constant speed.



34.3 Magnetic Flux

Faraday found that a current is induced when the amount of magnetic field passing through a coil or a loop of wire changes. And that's exactly what happens as the slide wire moves down the rail in Figure 34.5! As the circuit expands, more magnetic field passes through. It's time to define more clearly what we mean by "the amount of field passing through a loop."

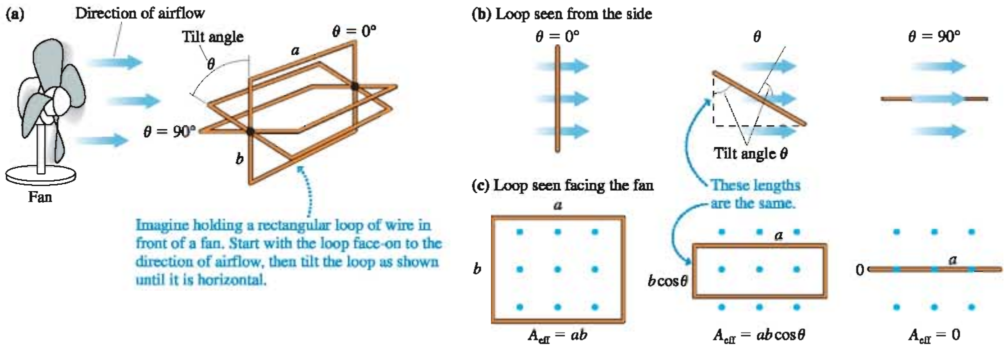
Imagine holding a rectangular loop of wire in front of a fan, as shown in FIGURE 34.12. The amount of air that flows through the loop depends on the effective area of the loop

as seen along the direction of flow. You can see from the figure that the effective area (i.e., as seen facing the fan) is

$$A_{\text{eff}} = ab\cos\theta = A\cos\theta \tag{34.8}$$

where $A = ab$ is the area of the loop and θ is the tilt angle of the loop. A loop perpendicular to the flow, with $\theta = 0°$, has $A_{\text{eff}} = A$, the full area of the loop. No air at all flows through the loop if it is tilted 90°, and you can see that $A_{\text{eff}} = 0$ in this case.

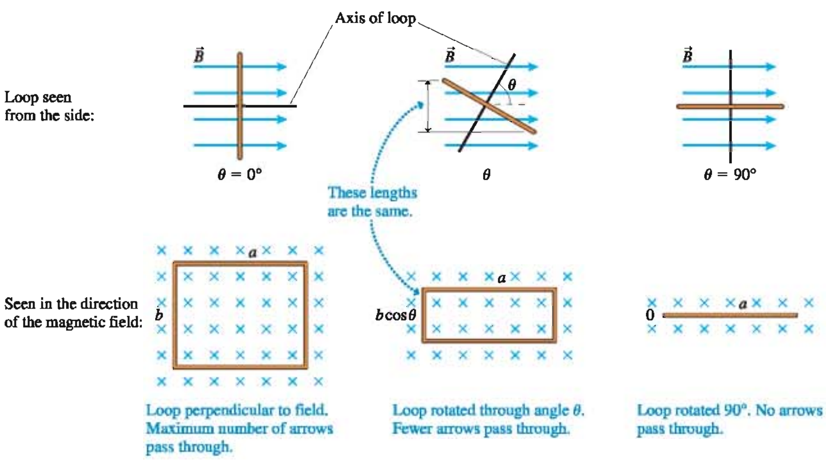
FIGURE 34.12 The amount of air flowing through a loop depends on the effective area of the loop.



We can apply this idea to a magnetic field passing through a loop. **FIGURE 34.13** shows a loop of area $A = ab$ in a uniform magnetic field. Think of the field vectors, seen here from behind, as if they were arrows shot into the page. The density of arrows (arrows per m^2) is proportional to the strength B of the magnetic field; a stronger field would be represented by arrows spaced closer together. The number of arrows passing through a loop of wire depends on two factors:

1. The density of arrows, which is proportional to B, and
2. The effective area $A_{\text{eff}} = A\cos\theta$ of the loop.

FIGURE 34.13 Magnetic field through a loop that is tilted at various angles.



The angle θ is the angle between the magnetic field and the axis of the loop. The maximum number of arrows passes through the loop when it is perpendicular to the magnetic field ($\theta = 0°$). No arrows pass through the loop if it is tilted 90°.

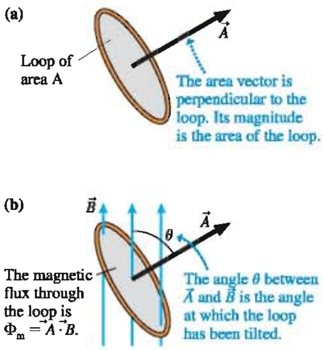
With this in mind, let's define the **magnetic flux** Φ_m as

$$\Phi_m = A_{eff}B = AB\cos\theta \qquad (34.9)$$

The magnetic flux measures the amount of magnetic field passing through a loop of area A if the loop is tilted at angle θ from the field. The SI unit of magnetic flux is the **weber.** From Equation 34.9 you can see that

$$1 \text{ weber} = 1 \text{ Wb} = 1 \text{ T m}^2$$

FIGURE 34.14 Magnetic flux can be defined in terms of an area vector $\vec{A}$.



Equation 34.9 is reminiscent of the vector dot product: $\vec{A}\cdot\vec{B} = AB\cos\theta$. With that in mind, let's define an **area vector** $\vec{A}$ to be a vector *perpendicular* to the loop magnitude equal to the area A of the loop. Vector $\vec{A}$ has units of m^2. FIGURE 34.14a shows the area vector $\vec{A}$ for a circular loop of area A.

FIGURE 34.14b shows a magnetic field passing through a loop. The angle between vectors $\vec{A}$ and $\vec{B}$ is the same angle used in Equations 34.8 and 34.9 to define the effective area and the magnetic flux. So Equation 34.9 really is a dot product, and we can define the magnetic flux more concisely as

$$\Phi_m = \vec{A}\cdot\vec{B} \qquad (34.10)$$

Writing the flux as a dot product helps make clear how angle θ is defined: θ is the angle between the magnetic field and the axis of the loop.

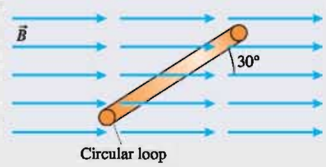
EXAMPLE 34.4 A circular loop in a magnetic field

FIGURE 34.15 is an edge view of a 10-cm-diameter circular loop in a uniform 0.050 T magnetic field. What is the magnetic flux through the loop?

SOLVE Angle θ is the angle between the loop's area vector $\vec{A}$, which is perpendicular to the plane of the loop, and the magnetic field $\vec{B}$. In this case, $\theta = 60°$, not the 30° angle shown in the figure. Vector $\vec{A}$ has magnitude $A = \pi r^2 = 7.85 \times 10^{-3}$ m^2. Thus the magnetic flux is

$$\Phi_m = \vec{A}\cdot\vec{B} = AB\cos\theta = 2.0 \times 10^{-4} \text{ Wb}$$

FIGURE 34.15 A circular loop in a magnetic field.



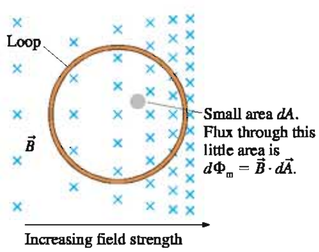
Magnetic Flux in a Nonuniform Field

Equation 34.10 for the magnetic flux assumes that the field is uniform over the area of the loop. We can calculate the flux in a nonuniform field, one where the field strength changes from one edge of the loop to the other, but we'll need to use calculus.

FIGURE 34.16 shows a loop in a nonuniform magnetic field. Imagine dividing the loop into many small pieces of area dA. The infinitesimal flux $d\Phi_m$ through one such area, where the magnetic field is $\vec{B}$, is

$$d\Phi_m = \vec{B}\cdot d\vec{A} \qquad (34.11)$$

FIGURE 34.16 A loop in a nonuniform magnetic field.



The total magnetic flux through the loop is the sum of the fluxes through each of the small areas. We find that sum by integrating. Thus the total magnetic flux through the loop is

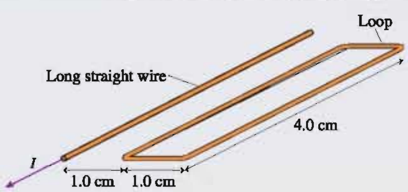
$$\Phi_m = \int_{\text{area of loop}} \vec{B}\cdot d\vec{A} \qquad (34.12)$$

Equation 34.12 is a more general definition of magnetic flux. It may look rather formidable, so we'll illustrate its use with an example.

EXAMPLE 34.5 Magnetic flux from the current in a long straight wire

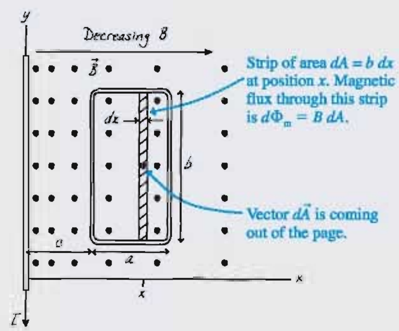
The 1.0 cm × 4.0 cm rectangular loop of FIGURE 34.17 is 1.0 cm away from a long straight wire. The wire carries a current of 1.0 A. What is the magnetic flux through the loop?

FIGURE 34.17 A loop next to a current carrying wire.



MODEL We'll treat the wire as if it were infinitely long. The magnetic field strength of a wire decreases with distance from the wire, so the field is *not* uniform over the area of the loop.

FIGURE 34.18 Calculating the magnetic flux through the loop.



VISUALIZE Using the right-hand rule, we see that the field, as it circles the wire, is perpendicular to the plane of the loop. FIGURE 34.18 redraws the loop with the field coming out of the page and establishes a coordinate system.

SOLVE Let the loop have dimensions a and b, as shown, with the near edge at distance c from the wire. The magnetic field varies with distance x from the wire, but the field is constant along a line parallel to the wire. This suggests dividing the loop into many narrow rectangular strips of length b and width dx, each forming a small area $dA = b\,dx$. The magnetic field has the same strength at all points within this small area. One such strip is shown in the figure at position x.

The area vector $d\vec{A}$ is perpendicular to the strip (coming out of the page), which makes it parallel to $\vec{B}$ ($\theta = 0°$). Thus the infinitesimal flux through this little area is

$$d\Phi_m = \vec{B} \cdot d\vec{A} = B\,dA = Bb\,dx = \frac{\mu_0 Ib}{2\pi x}\,dx$$

where, from Chapter 33, we've used $B = \mu_0 I/2\pi x$ as the magnetic field at distance x from a long straight wire. Integrating "over the area of the loop" means to integrate from the near edge of the loop at $x = c$ to the far edge at $x = c + a$. Thus

$$\Phi_m = \frac{\mu_0 Ib}{2\pi}\int_c^{c+a}\frac{dx}{x} = \frac{\mu_0 Ib}{2\pi}\ln x\Big|_c^{c+a} = \frac{\mu_0 Ib}{2\pi}\ln\left(\frac{c+a}{c}\right)$$

Evaluating for $a = c = 0.010$ m, $b = 0.040$ m, and $I = 1.0$ A gives

$$\Phi_m = 5.5 \times 10^{-9}\ \text{Wb}$$

ASSESS The flux measures how much of the wire's magnetic field passes through the loop, but we had to integrate, rather than simply using Equation 34.10, because the field is stronger at the near edge of the loop than at the far edge.

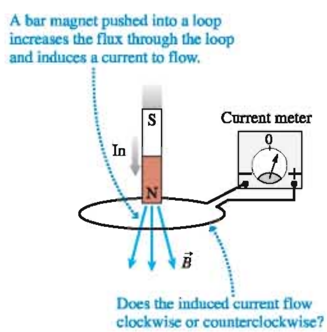
34.4 Lenz's Law

We started out by looking at a situation in which a moving wire caused a loop to expand in a magnetic field. This is one way to change the magnetic flux through the loop. But Faraday found that a current can be induced by any change in the magnetic flux, no matter how it's accomplished.

For example, a momentary current is induced in the loop of FIGURE 34.19 as the bar magnet is pushed toward the loop, increasing the flux through the loop. Pulling the magnet back out of the loop causes the current meter to deflect in the opposite direction. The conducting wires aren't moving, so this is not a motional emf. Nonetheless, the induced current is very real.

The German physicist Heinrich Lenz began to study electromagnetic induction after learning of Faraday's discovery. Three years later, in 1834, Lenz announced a rule for determining the direction of the induced current. We now call his rule **Lenz's law**, and it can be stated as follows:

FIGURE 34.19 Pushing a bar magnet toward the loop induces a current in the loop.



Lenz's law There is an induced current in a closed, conducting loop if and only if the magnetic flux through the loop is changing. The direction of the induced current is such that the induced magnetic field opposes the *change* in the flux.

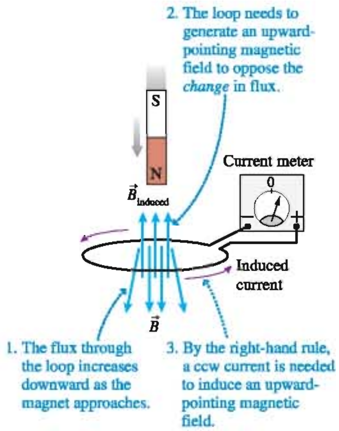
Lenz's law is rather subtle, and it takes some practice to see how to apply it.

NOTE ► One difficulty with Lenz's law is the term *flux*. In everyday language, the word *flux* already implies that something is changing. Think of the phrase, "The situation is in flux." Not so in physics, where *flux* means "passes through." A steady magnetic field through a loop creates a steady, *un*changing magnetic flux. ◄

Lenz's law tells us to look for situations where the flux is *changing*. This can happen in three ways.

1. The magnetic field through the loop changes (increases or decreases),
2. The loop changes in area or angle, or
3. The loop moves into or out of a magnetic field.

FIGURE 34.20 The induced current is ccw.

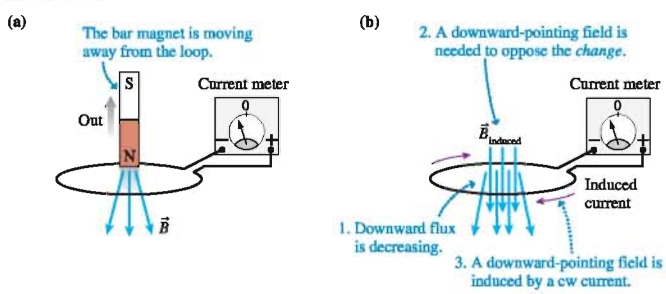


Lenz's law depends on an idea that we hinted at in our discussion of eddy currents. If a current is induced in a loop, that current generates its own magnetic field $\vec{B}_{induced}$. This is the *induced magnetic field* of Lenz's law. You learned in Chapter 33 how to use the right-hand rule to determine the direction of this induced magnetic field.

In Figure 34.19, pushing the bar magnet into the loop causes the magnetic flux to *increase* in the downward direction. To oppose the *change* in flux, which is what Lenz's law requires, the loop itself needs to generate the *upward*-pointing magnetic field of **FIGURE 34.20**. The induced magnetic field at the center of the loop will point upward if the current is ccw. Thus pushing the north end of a bar magnet toward the loop induces a ccw current around the loop. The induced current ceases as soon as the magnet stops moving.

Now suppose the bar magnet is pulled back away from the loop, as shown in **FIGURE 34.21a**. There is a downward magnetic flux through the loop, but the flux *decreases* as the magnet moves away. According to Lenz's law, the induced magnetic field of the loop *opposes this decrease*. To do so, the induced field needs to point in the *downward* direction, as shown in **FIGURE 34.21b**. Thus as the magnet is withdrawn, the induced current is clockwise (cw), opposite to the induced current of Figure 34.20.

FIGURE 34.21 Pulling the magnet away induces a cw current.

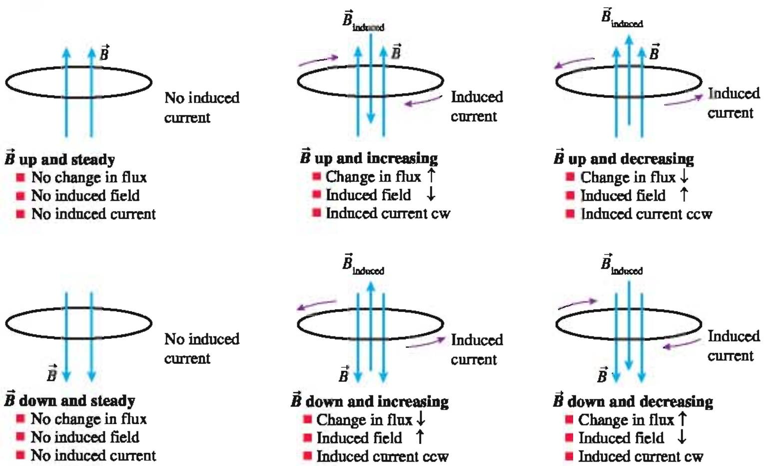


NOTE ► Notice that the magnetic field of the bar magnet is pointing downward in both Figures 34.20 and 34.21. It is not the *flux* due to the magnet that the induced current opposes, but the *change* in the flux. This is a subtle but critical distinction.

If the induced current opposed the flux itself, the current in both Figures 34.20 and 34.21 would be ccw to generate an upward magnetic field. But that's not what happens. When the field of the magnet points down and is increasing, the induced current opposes the increase by generating an upward field. When the field of the magnet points down but is decreasing, the induced current opposes the decrease by generating a downward field. ◀

FIGURE 34.22 shows six basic situations. The magnetic field can point either up or down through the loop. For each, the flux can either increase, hold steady, or decrease in strength. These observations form the basis for a set of rules about using Lenz's law.

FIGURE 34.22 The induced current for six different situations.



TACTICS BOX 34.1 Using Lenz's law

MP

1. **Determine the direction of the applied magnetic field.** The field must pass through the loop.
2. **Determine how the flux is changing.** Is it increasing, decreasing, or staying the same?
3. **Determine the direction of an induced magnetic field that will oppose the *change* in the flux.**
   - Increasing flux: the induced magnetic field points opposite the applied magnetic field.
   - Decreasing flux: the induced magnetic field points in the same direction as the applied magnetic field.
   - Steady flux: there is no induced magnetic field.
4. **Determine the direction of the induced current.** Use the right-hand rule to determine the current direction in the loop that generates the induced magnetic field you found in step 3.

Exercises 10–14

Let's look at some examples.

EXAMPLE 34.6 Lenz's law 1

The switch in the circuit of FIGURE 34.23 has been closed for a long time. What happens in the lower loop when the switch is opened?

MODEL We'll use the right-hand rule to find the magnetic fields of current loops.

SOLVE FIGURE 34.24 shows the four steps of using Lenz's law. Opening the switch induces a ccw current in the lower loop. This is a momentary current, lasting only until the magnetic field of the upper loop drops to zero.

ASSESS The conclusion is consistent with Figure 34.22.

FIGURE 34.23 Circuits of Example 34.6.

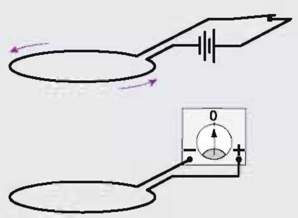


FIGURE 34.24 Applying Lenz's law.

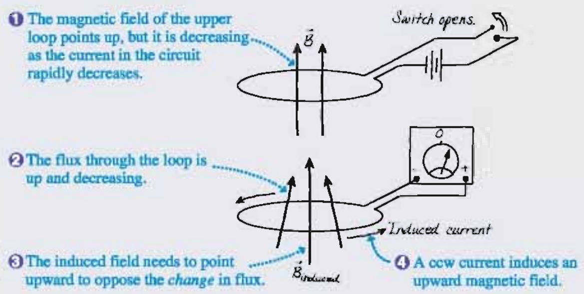

EXAMPLE 34.7 Lenz's law 2

FIGURE 34.25 shows two solenoids facing each other. When the switch for coil 1 is closed, does the induced current in coil 2 pass from right to left or from left to right through the current meter?

MODEL We'll use the right-hand rule to find the magnetic fields of solenoids.

VISUALIZE It is very important to look at the *direction* in which a solenoid is wound around the cylinder. Notice that the two solenoids in Figure 34.25 are wound in opposite directions.

SOLVE FIGURE 34.26 shows the four steps of using Lenz's law. Closing the switch induces a current that passes from right to left through the current meter. The induced current is only momentary. It lasts only until the field from coil 1 reaches full strength and is no longer changing.

ASSESS The conclusion is consistent with Figure 34.22.

FIGURE 34.25 The two solenoids of Example 34.7.

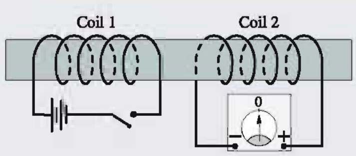

FIGURE 34.26 Applying Lenz's law.

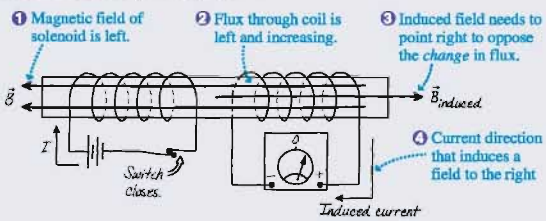
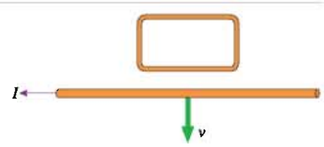


STOP TO THINK 34.4 A current-carrying wire is pulled away from a conducting loop in the direction shown. As the wire is moving, is there a cw current around the loop, a ccw current, or no current?



34.5 Faraday's Law

Faraday discovered that a current is induced when the magnetic flux through a conducting loop changes. Lenz's law allows us to find the direction of the induced current. To put electromagnetic induction to practical use, we also need to know the *size* of the induced current.

Activ Physics ONLINE 13.9, 13.10

Charges don't start moving spontaneously. A current requires an emf to provide the energy. We started our analysis of induced currents with circuits in which a *motional emf* can be understood in terms of magnetic forces on moving charges. But we've also seen that a current can be induced by changing the magnetic field through a stationary circuit, a circuit in which there is no motion. There *must* be an emf in this circuit, even though the mechanism for this emf is not yet clear.

The emf associated with a changing magnetic flux, regardless of what causes the change, is called an **induced emf** $\mathcal{E}$. Then, if there is a complete circuit having resistance R, a current

$$I_{\text{induced}} = \frac{\mathcal{E}}{R} \tag{34.13}$$

is established in the wire as a *consequence* of the induced emf. The direction of the current is given by Lenz's law. The last piece of information we need is the size of the induced emf $\mathcal{E}$.

The research of Faraday and others eventually led to the discovery of the basic law of electromagnetic induction, which we now call **Faraday's law.** Faraday's law is a new law of physics, not derivable from any previous laws you have studied. It states:

Faraday's law An emf $\mathcal{E}$ is induced around a closed loop if the magnetic flux through the loop changes. The magnitude of the emf is

$$\mathcal{E} = \left|\frac{d\Phi_{\text{m}}}{dt}\right| \tag{34.14}$$

and the direction of the emf is such as to drive an induced current in the direction given by Lenz's law.

In other words, the induced emf is the *rate of change* of the magnetic flux through the loop.

As a corollary to Faraday's law, a coil of wire consisting of N turns in a changing magnetic field acts like N batteries in series. The induced emf of each of the coils adds, so the induced emf of the entire coil is

$$\mathcal{E}_{\text{coil}} = N\left|\frac{d\Phi_{\text{per coil}}}{dt}\right| \quad \text{(Faraday's law for an } N\text{-turn coil)} \tag{34.15}$$

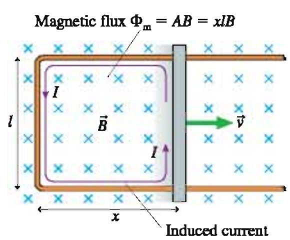
As a first example of using Faraday's law, return to the situation of Figure 34.5, where a wire moves through a magnetic field by sliding on a U-shaped conducting rail. **FIGURE 34.27** shows the circuit again. The magnetic field $\vec{B}$ is perpendicular to the plane of the conducting loop, so $\theta = 0°$ and the magnetic flux is $\Phi = AB$, where A is the area of the loop. If the slide wire is distance x from the end, the area is $A = xl$ and the flux at that instant of time is

$$\Phi_{\text{m}} = AB = xlB \tag{34.16}$$

The flux through the loop increases as the wire moves. According to Faraday's law, the induced emf is

$$\mathcal{E} = \left|\frac{d\Phi_{\text{m}}}{dt}\right| = \frac{d}{dt}(xlB) = \frac{dx}{dt}lB = vlB \tag{34.17}$$

FIGURE 34.27 The magnetic flux through the loop increases as the slide wire moves.



where the wire's velocity is $v = dx/dt$. We can now use Equation 34.13 to find that the induced current is

$$I = \frac{\mathcal{E}}{R} = \frac{vlB}{R} \tag{34.18}$$

The flux is increasing into the loop, so the induced magnetic field opposes this increase by pointing out of the loop. This requires a ccw induced current in the loop. Faraday's law leads us to the conclusion that the loop will have a ccw induced current $I = vlB/R$. This is exactly the conclusion we reached in Section 34.2, where we analyzed the situation from the perspective of magnetic forces on moving charge carriers. Faraday's law confirms what we already knew but, at least in this case, doesn't seem to offer anything new.

Using Faraday's Law

Most electromagnetic induction problems can be solved with a four-step strategy.

PROBLEM-SOLVING STRATEGY 34.1 Electromagnetic induction

MP

MODEL Make simplifying assumptions about wires and magnetic fields.

VISUALIZE Draw a picture or a circuit diagram. Use Lenz's law to determine the direction of the induced current.

SOLVE The mathematical representation is based on Faraday's law

$$\mathcal{E} = \left|\frac{d\Phi_m}{dt}\right|$$

For an N-turn coil, multiply by N. The size of the induced current is $I = \mathcal{E}/R$.

ASSESS Check that your result has the correct units, is reasonable, and answers the question.

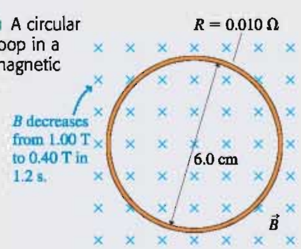
EXAMPLE 34.8 Electromagnetic induction in a loop

A patient having an MRI scan has neglected to remove a copper bracelet. The bracelet is 6.0 cm in diameter and has a resistance of 0.010 Ω. The magnetic field in the MRI solenoid is directed along the person's body from head to foot; the bracelet is perpendicular to $\vec{B}$. As a scan is taken, the magnetic field in the solenoid decreases from 1.00 T to 0.40 T in 1.2 s. What are the magnitude and direction of the current induced in the bracelet?

MODEL Assume that B decreases linearly with time.

VISUALIZE FIGURE 34.28 shows the bracelet and the applied field looking down along the patient's body. As the applied field decreases, the flux into the loop decreases. To oppose the decreasing flux, the field from the induced current must be in the direction of the applied field. Thus, from the right-hand rule, the induced current in the bracelet must be clockwise.

FIGURE 34.28 A circular conducting loop in a decreasing magnetic field.



SOLVE The magnetic field is perpendicular to the plane of the loop, hence $\theta = 0°$ and the magnetic flux is $\Phi_m = AB = \pi r^2 B$. The radius of the loop doesn't change with time, but B does. According to Faraday's law, the magnitude of the induced emf is

$$\mathcal{E} = \left|\frac{d\Phi_m}{dt}\right| = \pi r^2 \left|\frac{dB}{dt}\right|$$

The rate at which the magnetic field changes is

$$\frac{dB}{dt} = \frac{\Delta B}{\Delta t} = \frac{-0.60\ \text{T}}{1.2\ \text{s}} = -0.50\ \text{T/s}$$

dB/dt is negative because the field is decreasing, but all we need for Faraday's law is the absolute value. Thus

$$\mathcal{E} = \pi r^2 \left|\frac{dB}{dt}\right| = \pi(0.030\ \text{m})^2(0.50\ \text{T/s}) = 0.0014\ \text{V}$$

The current induced by this emf is

$$I = \frac{\mathcal{E}}{R} = \frac{0.0014\ \text{V}}{0.010\ \Omega} = 0.14\ \text{A}$$

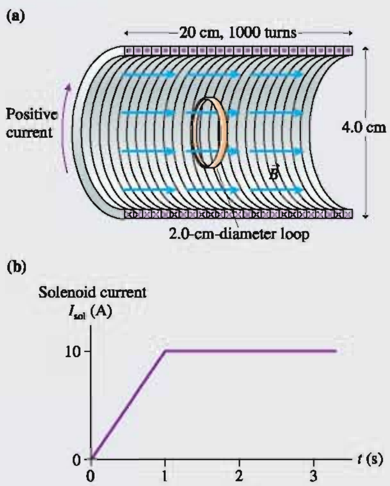
The decreasing magnetic field causes a 0.14 A clockwise current lasting for 1.2 s.

ASSESS The emf is quite small, but, because the resistance of a metal bracelet is also very small, the current is respectable. We know that electromagnetic induction produces currents large enough for practical applications, so this result seems plausible. The magnetic field of the induced current could easily distort the readings of the MRI machine. Consequently, operators are careful to have patients remove all metal before an MRI.

EXAMPLE 34.9 Electromagnetic induction in a solenoid

A 2.0-cm-diameter loop of wire with a resistance of 0.010 Ω is placed in the center of the solenoid seen in FIGURE 34.29a. The solenoid is 4.0 cm in diameter, 20 cm long, and wrapped with 1000 turns of wire. FIGURE 34.29b shows the current through the solenoid as a function of time as the solenoid is "powered up." A positive current is defined to be cw when seen from the left. Find the current in the loop as a function of time and show the result as a graph.

FIGURE 34.29 A loop inside a solenoid.



MODEL The solenoid's length is much greater than its diameter, so the field near the center should be nearly uniform.

VISUALIZE The magnetic field of the solenoid creates a magnetic flux through the loop of wire. The solenoid current is always positive, meaning that it is cw as seen from the left. Consequently, from the right-hand rule, the magnetic field inside the solenoid always points to the right. During the first second, while the solenoid current is increasing, the flux through the loop is to the right and increasing. To oppose the *change* in the flux, the loop's induced magnetic field must point to the left. Thus, again using the right-hand rule, the induced current must flow ccw as seen from the left. This is a *negative* current. There's no *change* in the flux for $t > 1$ s, so the induced current is zero.

SOLVE Now we're ready to use Faraday's law to find the magnitude of the current. Because the field is uniform inside the solenoid and perpendicular to the loop ($\theta = 0°$), the flux is $\Phi_m = AB$, where $A = \pi r^2 = 3.14 \times 10^{-4}\ \text{m}^2$ is the area of the loop (*not* the area of the solenoid). The field of a long solenoid of length l was found in Chapter 33 to be

$$B = \frac{\mu_0 N I_{sol}}{l}$$

The flux when the solenoid current is I_{sol} is thus

$$\Phi_m = \frac{\mu_0 A N I_{sol}}{l}$$

The changing flux creates an induced emf $\mathcal{E}$ that is given by Faraday's law:

$$\mathcal{E} = \left|\frac{d\Phi_m}{dt}\right| = \frac{\mu_0 A N}{l}\left|\frac{dI_{sol}}{dt}\right| = 2.0 \times 10^{-6}\left|\frac{dI_{sol}}{dt}\right|$$

From the slope of the graph, we find

$$\left|\frac{dI_{sol}}{dt}\right| = \begin{cases} 10\ \text{A/s} & 0.0\ \text{s} < t < 1.0\ \text{s} \\ 0 & 1.0\ \text{s} < t < 3.0\ \text{s} \end{cases}$$

Thus the induced emf is

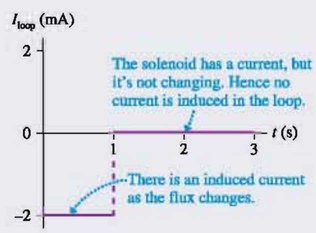
$$\mathcal{E} = \begin{cases} 2.0 \times 10^{-5}\ \text{V} & 0.0\ \text{s} < t < 1.0\ \text{s} \\ 0\ \text{V} & 1.0\ \text{s} < t < 3.0\ \text{s} \end{cases}$$

Finally, the current induced in the loop is

$$I_{loop} = \frac{\mathcal{E}}{R} = \begin{cases} -2.0\ \text{mA} & 0.0\ \text{s} < t < 1.0\ \text{s} \\ 0\ \text{mA} & 1.0\ \text{s} < t < 3.0\ \text{s} \end{cases}$$

where the negative sign comes from Lenz's law. This result is shown in FIGURE 34.30.

FIGURE 34.30 The induced current in the loop.



What Does Faraday's Law Tell Us?

The induced current in the slide-wire circuit of Figure 34.27 can be understood as a motional emf due to magnetic forces on moving charges. We had not anticipated this kind of current in Chapter 33, but it takes no new laws of physics to understand it.

The induced currents in Examples 34.8 and 34.9 are different. We cannot explain or predict these induced currents on the basis of previous laws or principles. This is new physics.

Faraday recognized that all induced currents are associated with a changing magnetic flux. There are two fundamentally different ways to change the magnetic flux through a conducting loop:

1. The loop can move or expand or rotate, creating a motional emf.
2. The magnetic field can change.

We can see both of these if we write Faraday's law as

$$\mathcal{E} = \left|\frac{d\Phi_m}{dt}\right| = \left|\vec{B}\cdot\frac{d\vec{A}}{dt} + \vec{A}\cdot\frac{d\vec{B}}{dt}\right| \tag{34.19}$$

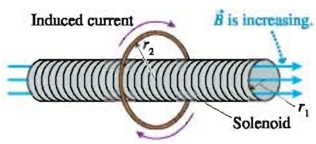
The first term on the right side represents a motional emf. The magnetic flux changes because the loop itself is changing. This term includes not only situations like the slide-wire circuit, where the area A changes, but also loops that rotate in a magnetic field. The physical area of a rotating loop does not change, but the area *vector* $\vec{A}$ does. The loop's motion causes magnetic forces on the charge carriers in the loop.

The second term on the right side is the new physics in Faraday's law. It says that an emf can also be created simply by changing a magnetic field, even if nothing is moving. This was the case in Examples 34.8 and 34.9.

Faraday's law tells us that the induced emf is simply the rate of change of the magnetic flux through the loop, *regardless* of what causes the flux to change. The "old physics" of motional emf is included within Faraday's law as one way of changing the flux, but Faraday's law then goes on to say that any other way of changing the flux will have the same result.

An Unanswered Question

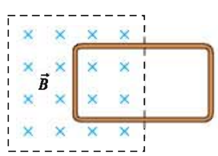
FIGURE 34.31 A changing current in the solenoid induces a current in the loop.



As a final example in this section, consider the loop shown in **FIGURE 34.31**. A long, tightly wound solenoid of radius r_1 passes through the center of a conducting loop having a larger radius r_2. Even though the loop is completely outside the magnetic field of the solenoid, changing the current through the solenoid causes an induced current around the loop.

How can the charge carriers in the conducting loop possibly know that the magnetic field inside the solenoid is changing? How do they know which way to move? In the case of a motional emf, the *mechanism* that causes an induced current is the magnetic force on the moving charges. But here, where there's no motion, what is the mechanism that creates a current when the magnetic flux changes? This is an important question, one that we will answer in the next section.

STOP TO THINK 34.5 A conducting loop is halfway into a magnetic field. Suppose the magnetic field begins to increase rapidly in strength. What happens to the loop?



a. The loop is pushed upward, toward the top of the page.
b. The loop is pushed downward, toward the bottom of the page.
c. The loop is pulled to the left, into the magnetic field.
d. The loop is pushed to the right, out of the magnetic field.
e. The tension in the wires increases but the loop does not move.

34.6 Induced Fields

Faraday's law is a tool for calculating the strength of an induced current, but one important piece of the puzzle is still missing. What *causes* the current? That is, what *force* pushes the charges around the loop against the resistive forces of the metal? The agents that exert forces on charges are electric fields and magnetic fields. Magnetic forces are responsible for motional emfs, but magnetic forces cannot explain the current induced in a *stationary* loop by a changing magnetic field.

FIGURE 34.32a shows a conducting loop in an increasing magnetic field. According to Lenz's law, there is an induced current in the ccw direction. Something has to act on the charge carriers to make them move, so we infer that there must be an *electric* field tangent to the loop at all points. This electric field is *caused* by the changing magnetic field and is called an **induced electric field.** The induced electric field is the *mechanism* that creates a current inside a stationary loop when there's a changing magnetic field.

The conducting loop isn't necessary. The space in which the magnetic field is changing is filled with the pinwheel pattern of induced electric fields shown in FIGURE 34.32b. Charges will move if a conducting path is present, but the induced electric field is there as a direct consequence of the changing magnetic field.

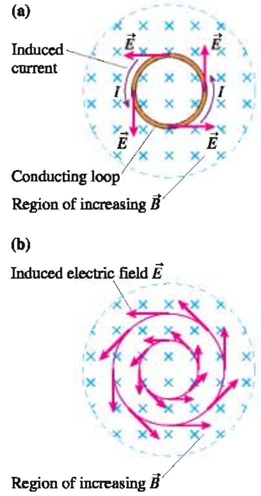


FIGURE 34.32 An induced electric field creates a current in the loop.

But this is a rather peculiar electric field. All the electric fields we have examined until now have been created by charges. Electric field vectors pointed away from positive charges and toward negative charges. An electric field created by charges is called a **Coulomb electric field.** The induced electric field of Figure 34.32b is caused not by charges but by a changing magnetic field. It is called a **non-Coulomb electric field.**

So it appears that there are two different ways to create an electric field:

1. A Coulomb electric field is created by positive and negative charges.
2. A non-Coulomb electric field is created by a changing magnetic field.

Both exert a force $\vec{F} = q\vec{E}$ on a charge, and both create a current in a conductor. However, the origins of the fields are very different. FIGURE 34.33 is a quick summary of the two ways to create an electric field.

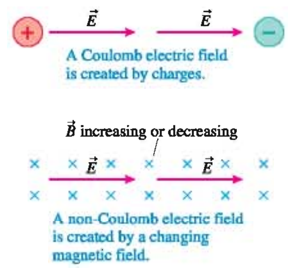

FIGURE 34.33 Two ways to create an electric field.

We first introduced the idea of a field as a way of thinking about how two charges exert long-range forces on each other through the emptiness of space. The field may have seemed like a useful pictorial representation of charge interactions, but we had little evidence that fields are *real,* that they actually exist. Now we do. The electric field has shown up in a completely different context, independent of charges, as the explanation of the very real existence of induced currents.

The electric field is not just a pictorial representation; it is real.

Calculating the Induced Field

The induced electric field is peculiar in another way: It is nonconservative. Recall that a force is conservative if it does no net work on a particle moving around a closed path. "Uphills" are balanced by "downhills." We can associate a potential energy with a conservative force, hence we have gravitational potential energy for the conservative gravitational force and electric potential energy for the conservative electric force of charges (a Coulomb electric field).

But a charge moving around a closed path in the induced electric field of Figure 34.32 is always being pushed *in the same direction* by the electric force $\vec{F} = q\vec{E}$. There's never any negative work to balance the positive work, so the net work done in going around a closed path is not zero. Because it's nonconservative, we cannot associate an electric potential with an induced electric field. Only the Coulomb field of charges has an electric potential.

However, we can associate the induced field with the emf of Faraday's law. The emf was defined as the work required per unit charge to separate the charge. That is,

$$\mathcal{E} = \frac{W}{q} \tag{34.20}$$

In batteries, a familiar source of emf, this work is done by chemical forces. But the emf that appears in Faraday's law arises when work is done by the force of an induced electric field.

If a charge q moves through a small displacement $d\vec{s}$, the small amount of work done by the electric field is $dW = \vec{F} \cdot d\vec{s} = q\vec{E} \cdot d\vec{s}$. The emf of Faraday's law is an emf around a *closed curve* through which the magnetic flux Φ_m is changing. The work done by the induced electric field as charge q moves around a closed curve is

$$W_{\text{closed curve}} = q\oint \vec{E} \cdot d\vec{s} \tag{34.21}$$

where the integration symbol with the circle is the same as the one we used in Ampère's law to indicate an integral around a closed curve. If we use this work in Equation 34.20, we find that the emf around a closed loop is

$$\mathcal{E} = \frac{W_{\text{closed curve}}}{q} = \oint \vec{E} \cdot d\vec{s} \tag{34.22}$$

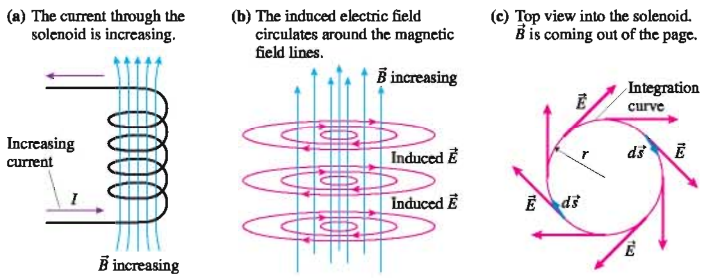
If we restrict ourselves to situations such as Figure 34.32 where the loop is perpendicular to the magnetic field and only the field is changing, we can write Faraday's law as $\mathcal{E} = |d\Phi_m/dt| = A|dB/dt|$. Consequently

$$\oint \vec{E} \cdot d\vec{s} = A\left|\frac{dB}{dt}\right| \tag{34.23}$$

Equation 34.23 is an alternative statement of Faraday's law that relates the induced electric field to the changing magnetic field.

The solenoid in FIGURE 34.34a provides a good example of the connection between $\vec{E}$ and $\vec{B}$. If there were a conducting loop inside the solenoid, we could use Lenz's law to determine that the direction of the induced current would be clockwise. But Faraday's law, in the form of Equation 34.23, tells us that **an induced electric field is present whether there's a conducting loop or not.** The electric field is induced simply due to the fact that $\vec{B}$ is changing.

FIGURE 34.34 The induced electric field circulates around the changing magnetic field inside a solenoid.



The shape and direction of the induced electric field have to be such that it *could* drive a current around a conducting loop, if one were present, and it has to be consistent with the cylindrical symmetry of the solenoid. The only possible choice, shown in FIGURE 34.34b, is an electric field that circulates clockwise around the magnetic field lines.

NOTE ▶ Circular electric field lines violate the Chapter 27 rule that electric field lines have to start and stop on charges. However, that rule applied only to Coulomb fields created by source charges. An induced electric field is a non-Coulomb field created not by source charges but by a changing magnetic field. Without source charges, induced electric field lines *must* form closed loops. ◀

To use Faraday's law, choose a *clockwise* circle of radius r as the closed curve for evaluating the integral. FIGURE 34.34c shows that the electric field vectors are everywhere tangent to the curve, so the line integral of $\vec{E}$ is

$$\oint \vec{E} \cdot d\vec{s} = El = 2\pi r E \tag{34.24}$$

where $l = 2\pi r$ is the length of the closed curve. This is exactly like the integrals we did for Ampère's law in Chapter 33.

If we stay inside the solenoid ($r < R$), the flux passes through area $A = \pi r^2$ and Equation 34.23 becomes

$$\oint \vec{E} \cdot d\vec{s} = 2\pi r E = A\left|\frac{dB}{dt}\right| = \pi r^2\left|\frac{dB}{dt}\right| \tag{34.25}$$

Thus the strength of the induced electric field inside the solenoid is

$$E_{\text{inside}} = \frac{r}{2}\left|\frac{dB}{dt}\right| \tag{34.26}$$

This result shows very directly that the induced electric field is created by a *changing* magnetic field. A constant $\vec{B}$, with $dB/dt = 0$, would give $E = 0$.

EXAMPLE 34.10 An induced electric field

A 4.0-cm-diameter solenoid is wound with 2000 turns per meter. The current through the solenoid oscillates at 60 Hz with an amplitude of 2.0 A. What is the maximum strength of the induced electric field inside the solenoid?

MODEL Assume that the magnetic field inside the solenoid is uniform.

VISUALIZE The electric field lines are concentric circles around the magnetic field lines, as was shown in Figure 34.34b. They reverse direction twice every period as the current oscillates.

SOLVE You learned in Chapter 33 that the magnetic field strength inside a solenoid with n turns per meter is $B = \mu_0 nI$. In this case, the current through the solenoid is $I = I_0 \sin\omega t$, where $I_0 = 2.0$ A is the peak current and $\omega = 2\pi(60 \text{ Hz}) = 377$ rad/s. Thus the induced electric field strength at radius r is

$$E = \frac{r}{2}\left|\frac{dB}{dt}\right| = \frac{r}{2}\frac{d}{dt}(\mu_0 n I_0 \sin\omega t) = \frac{1}{2}\mu_0 n r \omega I_0 \cos\omega t$$

The field strength is maximum at maximum radius ($r = R$) *and* at the instant when $\cos\omega t = 1$. That is,

$$E_{\text{max}} = \frac{1}{2}\mu_0 n R \omega I_0 = 0.019 \text{ V/m}$$

ASSESS This field strength, although not large, is similar to the field strength that the emf of a battery creates in a wire. Hence this induced electric field can drive a substantial induced current through a conducting loop *if* a loop is present. But the induced electric field exists inside the solenoid whether or not there is a conducting loop.

Occasionally it is useful to have a version of Faraday's law without the absolute value signs. The essence of Lenz's law is that the emf $\mathcal{E}$ opposes the *change* in Φ_m. Mathematically, this means that $\mathcal{E}$ must be opposite in sign to dB/dt. Consequently, we can write Faraday's law as

$$\mathcal{E} = \oint \vec{E} \cdot d\vec{s} = -\frac{d\Phi_m}{dt} \tag{34.27}$$

For practical applications, it's always easier to calculate just the magnitude of the emf with Faraday's law and to use Lenz's law to find the direction of the emf or the induced current. However, the mathematically rigorous version of Faraday's law in Equation 34.27 will prove to be useful when we combine it with other equations, in Chapter 35, to predict the existence of electromagnetic waves.

FIGURE 34.35 Maxwell hypothesized the existence of induced magnetic fields.

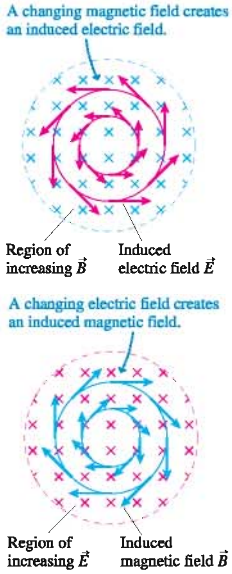


FIGURE 34.36 A self-sustaining electromagnetic wave.

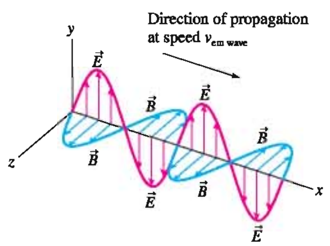


The velocity of transverse undulations in our hypothetical medium, calculated from the electromagnetic experiments of Kohlrausch and Weber [who had measured ϵ_0 and μ_0], agrees so exactly with the velocity of light calculated from the optical experiments of Fizeau that we can scarcely avoid the inference that light consists of the transverse undulations of the same medium which is the cause of electric and magnetic phenomena.

James Clerk Maxwell

Maxwell's Theory of Electromagnetic Waves

In 1855, less than two years after receiving his undergraduate degree, the Scottish physicist James Clerk Maxwell presented a paper titled "On Faraday's Lines of Force." In this paper, he began to sketch out how Faraday's pictorial ideas about fields could be given a rigorous mathematical basis. Maxwell was troubled by a certain lack of symmetry. Faraday had found that a changing magnetic field creates an induced electric field, a non-Coulomb electric field not tied to charges. But what, Maxwell began to wonder, about a changing *electric* field?

To complete the symmetry, Maxwell proposed that a changing electric field creates an **induced magnetic field**, a new kind of magnetic field not tied to the existence of currents. FIGURE 34.35 shows a region of space where the *electric* field is increasing. This region of space, according to Maxwell, is filled with a pinwheel pattern of induced magnetic fields. The induced magnetic field looks like the induced electric field, with $\vec{E}$ and $\vec{B}$ interchanged, except that—for technical reasons explored in the next chapter—the induced $\vec{B}$ points the opposite way from the induced $\vec{E}$. Although there was no experimental evidence that induced magnetic fields existed, Maxwell went ahead and included them in his electromagnetic field theory. This was an inspired hunch, soon to be vindicated.

Maxwell soon realized that it might be possible to establish self-sustaining electric and magnetic fields that would be entirely independent of any charges or currents. That is, a changing electric field $\vec{E}$ creates a magnetic field $\vec{B}$, which then changes in just the right way to recreate the electric field, which then changes in just the right way to again recreate the magnetic field, and so on. The fields are continually recreated through electromagnetic induction without any reliance on charges or currents.

Maxwell was able to predict that electric and magnetic fields would be able to sustain themselves, free from charges and currents, if they took the form of an **electromagnetic wave.** The wave would have to have a very specific geometry, shown in FIGURE 34.36, in which $\vec{E}$ and $\vec{B}$ are perpendicular to each other as well as perpendicular to the direction of travel. That is, an electromagnetic wave would be a *transverse* wave.

Furthermore, Maxwell's theory predicted that the wave would travel with speed

$$v_{\text{em wave}} = \frac{1}{\sqrt{\epsilon_0 \mu_0}}$$

where ϵ_0 is the permittivity constant from Coulomb's law and μ_0 is the permeability constant from the law of Biot and Savart. Maxwell computed that an electromagnetic wave, if it existed, would travel with speed $v_{\text{em wave}} = 3.00 \times 10^8$ m/s.

We don't know Maxwell's immediate reaction, but it must have been both shock and excitement. His predicted speed for electromagnetic waves, a prediction that came directly from his theory, was none other than the speed of light! This agreement could be just a coincidence, but Maxwell didn't think so. Making a bold leap of imagination, Maxwell concluded that **light is an electromagnetic wave.**

It took 25 more years for Maxwell's predictions to be tested. In 1886, the German physicist Heinrich Hertz discovered how to generate and transmit radio waves. Two years later, in 1888, he was able to show that radio waves travel at the speed of light. Maxwell, unfortunately, did not live to see his triumph. He had died in 1879, at the age of 48.

Chapter 35 will develop some of the mathematical details of Maxwell's theory and show how the ideas contained in Faraday's law lead to electromagnetic waves.

34.7 Induced Currents: Three Applications

There are many applications of Faraday's law and induced currents in modern technology. In this section we will look at three: generators, transformers, and metal detectors.

Generators

We noted in Section 34.2 that a slide wire pulled through a magnetic field on a U-shaped track is a simple generator because it transforms mechanical energy into electric energy. FIGURE 34.37 shows a more practical generator. Here a coil of wire, perhaps spun by a windmill, rotates in a magnetic field. Both the field and the area of the loop are constant, but the magnetic flux through the loop changes continuously as the loop rotates. The induced current is removed from the rotating loop by ***brushes*** that press up against rotating ***slip rings***.

The flux through the coil is

$$\Phi_m = \vec{A}\cdot\vec{B} = AB\cos\theta = AB\cos\omega t \qquad (34.28)$$

where ω is the angular frequency ($\omega = 2\pi f$) with which the coil rotates. The induced emf is given by Faraday's law,

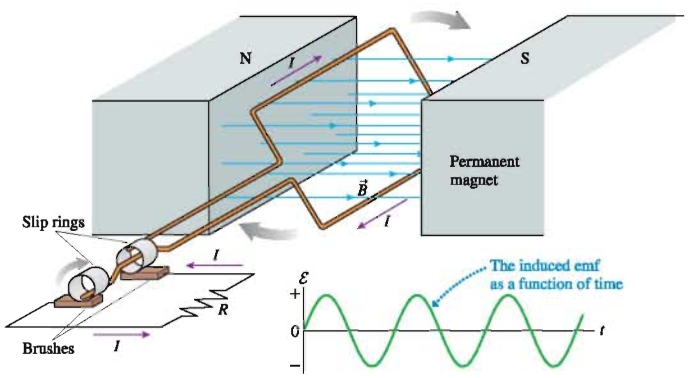
$$\mathcal{E}_{\text{coil}} = -N\frac{d\Phi_m}{dt} = -ABN\frac{d}{dt}(\cos\omega t) = \omega ABN\sin\omega t \qquad (34.29)$$

where N is the number of turns on the coil. Here it's best to use the signed version of Faraday's law, Equation 34.27, to see how the sign of $\mathcal{E}_{\text{coil}}$ alternates between positive and negative.

Because the emf alternates in sign, the current through resistor R alternates back and forth in direction. Hence the generator of Figure 34.37 is an alternating-current generator, producing what we call an *AC voltage.*

A generator inside a hydroelectric dam uses electromagnetic induction to convert the mechanical energy of a spinning turbine into electric energy.

FIGURE 34.37 An alternating-current generator.



EXAMPLE 34.11 An AC generator

A coil with area 2.0 m^2 rotates in a 0.010 T magnetic field at a frequency of 60 Hz. How many turns are needed to generate a peak voltage of 160 V?

SOLVE The coil's maximum voltage is found from Equation 34.29:

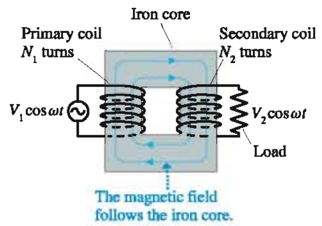
$$\mathcal{E}_{\max} = \omega ABN = 2\pi fABN$$

The number of turns needed to generate $\mathcal{E}_{\max} = 160$ V is

$$N = \frac{\mathcal{E}_{\max}}{2\pi fAB} = \frac{160\text{ V}}{2\pi(60\text{ Hz})(2.0\text{ m}^2)(0.010\text{ T})} = 21\text{ turns}$$

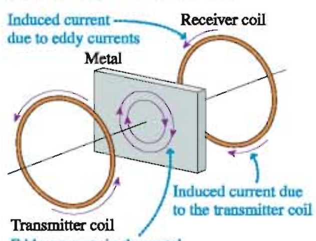
ASSESS A 0.010 T field is modest, so you can see that generating large voltages is not difficult with large (2 m^2) coils. Commercial generators use water flowing through a dam, rotating windmill blades, or turbines spun by expanding steam to rotate the generator coils. Work is required to rotate the coil, just as work was required to pull the slide wire in Section 34.2, because the magnetic field exerts retarding forces on the currents in the coil. Thus a generator is a device that turns motion (mechanical energy) into a current (electric energy). A generator is the opposite of a motor, which turns a current into motion.

FIGURE 34.38 A transformer.



Transformers are essential for transporting electric energy from the power plant to cities and homes.

FIGURE 34.39 A metal detector.



Transformers

FIGURE 34.38 shows two coils wrapped on an iron core. The left coil is called the **primary coil.** It has N_1 turns and is driven by an oscillating voltage $V_1 \cos\omega t$. The magnetic field of the primary follows the iron core and passes through the right coil, which has N_2 turns and is called the **secondary coil.** The alternating current through the primary coil causes an oscillating magnetic flux through the secondary coil and, hence, an induced emf. The induced emf of the secondary coil is delivered to the load as the oscillating voltage $V_2 \cos\omega t$.

The changing magnetic field inside the iron core is inversely proportional to the number of turns on the primary coil: $B \propto 1/N_1$. (This relation is a consequence of the coil's inductance, an idea discussed in the next section.) According to Faraday's law, the emf induced in the secondary coil is directly proportional to its number of turns: $\mathcal{E}_{sec} \propto N_2$. Combining these two proportionalities, the secondary voltage of an ideal transformer is related to the primary voltage by

$$V_2 = \frac{N_2}{N_1} V_1 \tag{34.30}$$

Depending on the ratio N_2/N_1, the voltage V_2 across the load can be *transformed* to a higher or a lower voltage than V_1. Consequently, this device is called a **transformer.** Transformers are widely used in the commercial generation and transmission of electricity. A *step-up transformer,* with $N_2 \gg N_1$, boosts the voltage of a generator up to several hundred thousand volts. Delivering power with smaller currents at higher voltages reduces losses due to the resistance of the wires. High-voltage transmission lines carry electric power to urban areas, where *step-down transformers* ($N_2 \ll N_1$) lower the voltage to 120 V.

Metal Detectors

Metal detectors, such as those used in airports for security, seem fairly mysterious. How can they detect the presence of *any* metal—not just magnetic materials such as iron—but not detect plastic or other materials? Metal detectors work because of induced currents.

A metal detector, shown in FIGURE 34.39, consist of two coils: a *transmitter coil* and a *receiver coil.* A high-frequency alternating current in the transmitter coil generates an alternating magnetic field along the axis. This magnetic field creates a changing flux through the receiver coil and causes an alternating induced current. The transmitter and receiver are similar to a transformer.

Suppose a piece of metal is placed between the transmitter and the receiver. The alternating magnetic field through the metal induces eddy currents in a plane parallel to the transmitter and receiver coils. The receiver coil then responds to the *superposition* of the transmitter's magnetic field and the magnetic field of the eddy currents. Because the eddy currents attempt to prevent the flux from changing, in accordance with Lenz's law, the net field at the receiver *decreases* when a piece of metal is inserted between the coils. Electronic circuits detect the current decrease in the receiver coil and set off an alarm. Eddy currents can't flow in an insulator, so this device detects only metals.

34.8 Inductors

Capacitors were first introduced as devices that produce a uniform electric field. The capacitance (i.e., the *capacity* to store charge) was defined as the charge-to-voltage ratio $C = Q/\Delta V$. We later found that a capacitor stores potential energy $U_C = \frac{1}{2}C(\Delta V)^2$ and that this energy is released when the capacitor is discharged.

A coil of wire in the form of a solenoid is a device that produces a uniform magnetic field. Do solenoids in circuits have practical uses, as capacitors do? As a starting

point to answering this question, notice that the charge on a capacitor is analogous to the magnetic flux through a solenoid. That is, a larger diameter capacitor plate holds more charge just as a larger diameter solenoid contains more flux. Using the definition of capacitance $C = Q/\Delta V$ as an analog, let's define the **inductance** L of a solenoid as its flux-to-current ratio

$$L = \frac{\Phi_m}{I} \tag{34.31}$$

Strictly speaking, this is called *self-inductance* because the flux we're considering is the magnetic flux the solenoid creates in itself when there is a current.

The units of inductance are Wb/A. Recalling that $1\ \text{Wb} = 1\ \text{T m}^2$, this is equivalent to $\text{T m}^2/\text{A}$. It's convenient to define an SI unit of inductance called the **henry,** in honor of Joseph Henry, as

$$1\ \text{henry} = 1\ \text{H} \equiv 1\ \text{T m}^2/\text{A}$$

Practical inductances are usually in the range of millihenries (mH) or microhenries (μH).

A coil of wire used in a circuit for the purpose of providing inductance is called an **inductor.** An *ideal inductor* is one for which the wire forming the coil has no electric resistance. The circuit symbol for an inductor is .

It's not hard to find the inductance of a solenoid. In Chapter 33 we found that the magnetic field inside a solenoid having N turns and length l is

$$B = \frac{\mu_0 N I}{l}$$

The magnetic flux through *each* coil is $\Phi_{\text{per coil}} = AB$, where A is the cross-section area of the solenoid. The total flux through all N coils is

$$\Phi_m = N\Phi_{\text{per coil}} = \frac{\mu_0 N^2 A}{l} I \tag{34.32}$$

Thus the inductance of the solenoid, using the definition of Equation 34.31, is

$$L_{\text{solenoid}} = \frac{\Phi_m}{I} = \frac{\mu_0 N^2 A}{l} \tag{34.33}$$

The inductance of a solenoid depends only on its geometry, not at all on the current. You may recall that the capacitance of two parallel plates depends only on their geometry, not at all on their potential difference.

EXAMPLE 34.12 The length of an inductor

An inductor is made by tightly wrapping 0.30-mm-diameter wire around a 4.0-mm-diameter cylinder. What length cylinder has an inductance of 10 μH?

SOLVE The cross-section area of the solenoid is $A = \pi r^2$. If the wire diameter is d, the number of turns of wire on a cylinder of length l is $N = l/d$. Thus the inductance is

$$L = \frac{\mu_0 N^2 A}{l} = \frac{\mu_0 (l/d)^2 \pi r^2}{l} = \frac{\mu_0 \pi r^2 l}{d^2}$$

The length needed to give inductance $L = 1.0 \times 10^{-5}$ H is

$$l = \frac{d^2 L}{\mu_0 \pi r^2} = \frac{(0.00030\ \text{m})^2 (1.0 \times 10^{-5}\ \text{H})}{(4\pi \times 10^{-7}\ \text{T m/A})\pi (0.0020\ \text{m})^2}$$
$$= 0.057\ \text{m} = 5.7\ \text{cm}$$

The Potential Difference Across an Inductor

An inductor is not very interesting when the current through it is steady. If the inductor is ideal, with $R = 0\ \Omega$, the potential difference due to a steady current is zero. Inductors become important circuit elements when currents are changing.

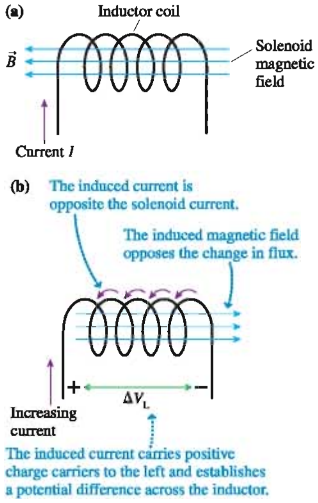


FIGURE 34.40 Increasing the current through an inductor.

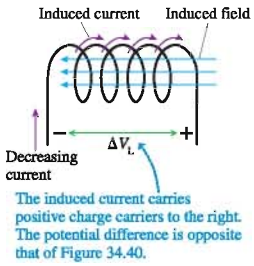

FIGURE 34.41 Decreasing the current through an inductor.

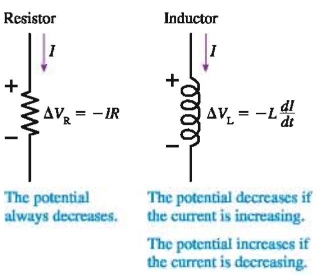

FIGURE 34.42 The potential difference across a resistor and an inductor.

FIGURE 34.40a shows a steady current into the left side of an inductor. The solenoid's magnetic field passes through the coils of the solenoid, establishing a flux.

In **FIGURE 34.40b**, the current into the solenoid is increasing. This creates an increasing flux to the left. According to Lenz's law, an induced current in the coils will oppose this increase by creating an induced magnetic field pointing to the right. This requires the induced current to be *opposite* the current into the solenoid. This induced current will carry positive charge carriers to the left until a potential difference is established across the solenoid.

You saw a similar situation in Section 34.2. The induced current in a conductor moving through a magnetic field carried positive charge carriers to the top of the wire and established a potential difference across the conductor. The induced current in the moving wire was due to magnetic forces on the moving charges. Now, in **FIGURE 34.40b**, the induced current is due to the non-Coulomb electric field induced by the changing magnetic field. Nonetheless, the outcome is the same: a potential difference across the conductor.

We can use Faraday's law to find the potential difference. The emf induced in a coil is

$$\mathcal{E}_{\text{coil}} = N\left|\frac{d\Phi_{\text{per coil}}}{dt}\right| = \left|\frac{d\Phi_m}{dt}\right| \tag{34.34}$$

where $\Phi = N\Phi_{\text{per coil}}$ is the total flux through all the coils. The inductance was defined such that $\Phi_m = LI$, so Equation 34.34 becomes

$$\mathcal{E}_{\text{coil}} = L\left|\frac{dI}{dt}\right| \tag{34.35}$$

The induced emf is directly proportional to the *rate of change* of current through the coil. We'll consider the appropriate sign in a moment, but Equation 34.35 gives us the size of the potential difference that is developed across a coil as the current through the coil changes. Note that $\mathcal{E}_{\text{coil}} = 0$ for a steady, unchanging current.

FIGURE 34.41 shows the same inductor, but now the current (still *in* to the left side) is decreasing. To oppose the decrease in flux, the induced current is in the *same* direction as the input current. The induced current carries charge to the right and establishes a potential difference opposite that in Figure 34.40b.

NOTE ▶ Notice that the induced current does not oppose the current through the inductor, which is from left to right in both Figures 34.40 and 34.41. Instead, in accordance with Lenz's law, the induced current opposes the *change* in the current in the solenoid. The practical result is that it is hard to change the current through an inductor. Any effort to increase or decrease the current is met with opposition in the form of an opposing induced current. You can think of the current in an inductor as having inertia, trying to continue what it was doing without change. ◀

Before we can use inductors in a circuit we need to establish a rule about signs that is consistent with our earlier circuit analysis. **FIGURE 34.42** first shows current I passing through a resistor. You learned in Chapter 32 that the potential difference across a resistor is $\Delta V_R = -IR$, where the minus sign indicates that the potential *decreases* in the direction of the current.

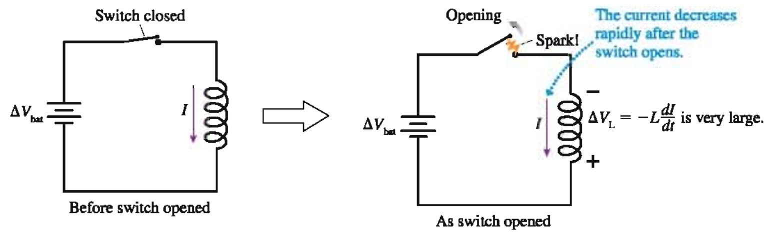
We'll use the same convention for an inductor. The potential difference across an inductor, measured along the direction of the current, is

$$\Delta V_L = -L\frac{dI}{dt} \tag{34.36}$$

If the current is increasing ($dI/dt > 0$), the input side of the inductor is more positive than the output side and the potential decreases in the direction of the current ($\Delta V_L < 0$). This was the situation in Figure 34.40b. If the current is decreasing ($dI/dt < 0$), the input side is more negative and the potential increases in the direction of the current ($\Delta V_L > 0$). This was the situation in Figure 34.41.

The potential difference across an inductor can be very large if the current changes very abruptly (large dI/dt). FIGURE 34.43 shows an inductor connected across a battery. There is a large current through the inductor, limited only by the internal resistance of the battery. Suppose the switch is suddenly opened. A very large induced voltage is created across the inductor as the current rapidly drops to zero. This potential difference (plus ΔV_{bat}) appears across the gap of the switch as it is opened. A large potential difference across a small gap often creates a spark.

FIGURE 34.43 Creating sparks.



Indeed, this is exactly how the spark plugs in your car work. The car's generator sends a large current through the *coil,* which is a big inductor. A switch in the *distributor* is suddenly opened, breaking the current. The induced voltage, typically a few thousand volts, appears across the terminals of the spark plug, creating the spark that ignites the gasoline. A similar phenomenon happens if you unplug appliances such as toaster ovens or hair dryers while they are running. The heating coils in these devices have quite a bit of inductance. Suddenly pulling the plug is like opening a switch. The large induced voltage often causes a spark between the plug and the electric outlet.

EXAMPLE 34.13 Large voltage across an inductor

A 1.0 A current passes through a 10 mH inductor coil. What potential difference is induced across the coil if the current drops to zero in 5.0 μs?

MODEL Assume this is an ideal inductor, with $R = 0\,\Omega$, and that the current decrease is linear with time.

SOLVE The rate of current decrease is

$$\frac{dI}{dt} \approx \frac{\Delta I}{\Delta t} = \frac{-1.0\text{ A}}{5.0 \times 10^{-6}\text{ s}} = -2.0 \times 10^{5}\text{ A/s}$$

The induced voltage is

$$\Delta V_L = -L\frac{dI}{dt} \approx -(0.010\text{ H})(-2.0 \times 10^{5}\text{ A/s}) = 2000\text{ V}$$

ASSESS Inductors may be physically small, but they can pack a punch if you try to change the current through them too quickly.

STOP TO THINK 34.6 The potential at a is higher than the potential at b. Which of the following statements about the inductor current I could be true?

a. I is from a to b and steady.
b. I is from a to b and increasing.
c. I is from a to b and decreasing.
d. I is from b to a and steady.
e. I is from b to a and increasing.
f. I is from b to a and decreasing.

Energy in Inductors and Magnetic Fields

An inductor, like a capacitor, stores energy that can later be released. It is energy released from the coil in your car that becomes the spark of the spark plug. You learned in Chapter 32 that electric power is $P_{elec} = I\,\Delta V$. As current passes through an inductor, for which $\Delta V_L = -L(dI/dt)$, the electric power is

$$P_{elec} = I\Delta V_L = -LI\frac{dI}{dt} \tag{34.37}$$

P_{elec} is negative because the current is *losing* electric energy. That energy is being transferred to the inductor, which is *storing* energy U_L at the rate

$$\frac{dU_L}{dt} = +LI\frac{dI}{dt} \tag{34.38}$$

where we've noted that power is the rate of change of energy.

We can find the total energy stored in an inductor by integrating Equation 34.38 from $I = 0$, where $U_L = 0$, to a final current I. Doing so gives

$$\boxed{U_L = L\int_0^I I\,dI = \frac{1}{2}LI^2} \tag{34.39}$$

The potential energy stored in an inductor depends on the square of the current through it. Notice the analogy with the energy $U_C = \frac{1}{2}C(\Delta V)^2$ stored in a capacitor.

In working with circuits we say that the energy is "stored in the inductor." Strictly speaking, the energy is stored in the inductor's magnetic field, analogous to how a capacitor stores energy in the electric field. We can use the inductance of a solenoid, Equation 34.33, to relate the inductor's energy to the magnetic field strength:

$$U_L = \frac{1}{2}LI^2 = \frac{\mu_0 N^2 A}{2l}I^2 = \frac{1}{2\mu_0}Al\left(\frac{\mu_0 NI}{l}\right)^2 \tag{34.40}$$

We made the last rearrangement in Equation 34.40 because $\mu_0 NI/l$ is the magnetic field inside the solenoid. Thus

$$U_L = \frac{1}{2\mu_0}AlB^2 \tag{34.41}$$

But Al is the volume inside the solenoid. Dividing by Al, the magnetic field *energy density* inside the solenoid (energy per m^3) is

$$u_B = \frac{1}{2\mu_0}B^2 \tag{34.42}$$

We've derived this expression for energy density based on the properties of a solenoid, but it turns out to be the correct expression for the energy density anywhere there's a magnetic field. Compare this to the energy density of an electric field $u_E = \frac{1}{2}\epsilon_0 E^2$ that we found in Chapter 30.

Energy in electric and magnetic fields

Electric fields	Magnetic fields
A capacitor stores energy	An inductor stores energy
$U_C = \frac{1}{2}C(\Delta V)^2$	$U_L = \frac{1}{2}LI^2$
Energy density in the field is	Energy density in the field is
$u_E = \frac{\epsilon_0}{2}E^2$	$u_B = \frac{1}{2\mu_0}B^2$

EXAMPLE 34.14 Energy stored in an inductor

The 10 μH inductor of Example 34.12 was 5.7 cm long and 4.0 mm in diameter. Suppose it carries a 100 mA current. What are the energy stored in the inductor, the magnetic energy density, and the magnetic field strength?

SOLVE The stored energy is

$$U_L = \frac{1}{2}LI^2 = \frac{1}{2}(1.0 \times 10^{-5}\ \text{H})(0.10\ \text{A})^2 = 5.0 \times 10^{-8}\ \text{J}$$

The solenoid volume is $(\pi r^2)l = 7.16 \times 10^{-7}\ \text{m}^3$. Using this gives the energy density of the magnetic field:

$$u_B = \frac{5.0 \times 10^{-8}\ \text{J}}{7.16 \times 10^{-7}\ \text{m}^3} = 0.070\ \text{J/m}^3$$

From Equation 34.42, the magnetic field with this energy density is

$$B = \sqrt{2\mu_0 u_B} = 4.2 \times 10^{-4}\ \text{T}$$

34.9 *LC* Circuits

Telecommunication—radios, televisions, cell phones—is based on electromagnetic signals that *oscillate* at a well-defined frequency. These oscillations are generated and detected by a simple circuit consisting of an inductor and a capacitor in parallel. This is called an ***LC* circuit.** In this section we will learn why an *LC* circuit oscillates and determine the oscillation frequency.

FIGURE 34.44 shows a capacitor with initial charge Q_0, an inductor, and a switch. The switch has been open for a long time, so there is no current in the circuit. Then, at $t = 0$, the switch is closed. How does the circuit respond? Let's think it through qualitatively before getting into the mathematics.

As FIGURE 34.45 shows, the inductor provides a conducting path for discharging the capacitor. However, the discharge current has to pass through the inductor, and, as we've seen, an inductor resists changes in current. Consequently, the current doesn't stop when the capacitor charge reaches zero.

FIGURE 34.44 An *LC* circuit.

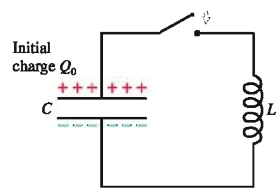


FIGURE 34.45 The capacitor charge oscillates much like a block attached to a spring.

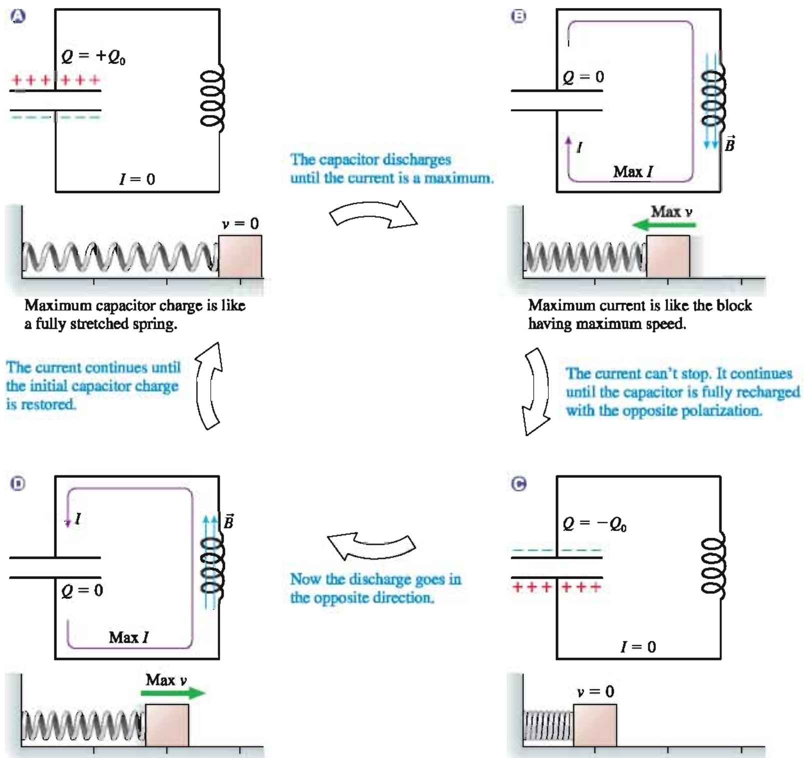


A block attached to a stretched spring is a useful mechanical analogy. Closing the switch to discharge the capacitor is like releasing the block. The block doesn't stop when it reaches the origin; its momentum keeps it going until the spring is fully compressed. Likewise, the current continues until it has recharged the capacitor with the opposite polarization. This process repeats over and over, charging the capacitor first one way, then the other. That is, the charge and current *oscillate*.

The goal of our circuit analysis will be to find expressions showing how the capacitor charge Q and the inductor current I change with time. As always, our starting point for circuit analysis is Kirchhoff's voltage law, which says that all the potential differences around a closed loop must sum to zero. Choosing a cw direction for I, Kirchhoff's law is

$$\Delta V_C + \Delta V_L = 0 \tag{34.43}$$

You learned in Chapter 30 that the potential difference across a capacitor is $\Delta V_C = Q/C$, where Q is the charge on the top plate of the capacitor, and we found the potential difference across an inductor in Equation 34.36 above. Using these, Kirchhoff's law becomes

$$\frac{Q}{C} - L\frac{dI}{dt} = 0 \tag{34.44}$$

A cell phone is actually a very sophisticated two-way radio that communicates with the nearest base station via high-frequency radio waves—roughly 1000 MHz. As in any radio or communications device, the transmission frequency is established by the oscillating current in an LC circuit.

Equation 34.44 has two unknowns, Q and I. We can eliminate one of the unknowns by finding another relation between Q and I. Current is the rate at which charge moves, $I = dq/dt$, but the charge flowing through the inductor is charge that was *removed* from the capacitor. That is, an infinitesimal charge dq flows through the inductor when the capacitor charge changes by $dQ = -dq$. Thus the current through the inductor is related to the charge on the capacitor by

$$I = -\frac{dQ}{dt} \tag{34.45}$$

Now I is positive when Q is decreasing, as we would expect. This is a subtle but important step in the reasoning, one worth thinking about because it appears in other contexts.

Equations 34.44 and 34.45 are two equations in two unknowns. To solve them, we'll first take the time derivative of Equation 34.45:

$$\frac{dI}{dt} = \frac{d}{dt}\left(-\frac{dQ}{dt}\right) = -\frac{d^2Q}{dt^2} \tag{34.46}$$

We can substitute this result into Equation 34.44:

$$\frac{Q}{C} + L\frac{d^2Q}{dt^2} = 0 \tag{34.47}$$

Now we have an equation for the capacitor charge Q.

Equation 34.47 is a second-order differential equation for Q. Fortunately, it is an equation we've seen before and already know how to solve. To see this, rewrite Equation 34.47 as

$$\frac{d^2Q}{dt^2} = -\frac{1}{LC}Q \tag{34.48}$$

Recall, from Chapter 14, that the equation of motion for an undamped mass on a spring is

$$\frac{d^2x}{dt^2} = -\frac{k}{m}x \tag{34.49}$$

Equation 34.48 is *exactly the same equation,* with x replaced by Q and k/m replaced by $1/LC$. This should be no surprise because we've already seen that a mass on a spring is a mechanical analog of the LC circuit.

We know the solution to Equation 34.49. It is simple harmonic motion $x(t) = x_0\cos\omega t$ with angular frequency $\omega = \sqrt{k/m}$. Thus the solution to Equation 34.48 must be

$$Q(t) = Q_0\cos\omega t \tag{34.50}$$

where Q_0 is the initial charge, at $t = 0$, and the angular frequency is

$$\omega = \sqrt{\frac{1}{LC}} \tag{34.51}$$

The charge on the upper plate of the capacitor oscillates back and forth between $+Q_0$ and $-Q_0$ (the opposite polarization) with period $T = 2\pi/\omega$.

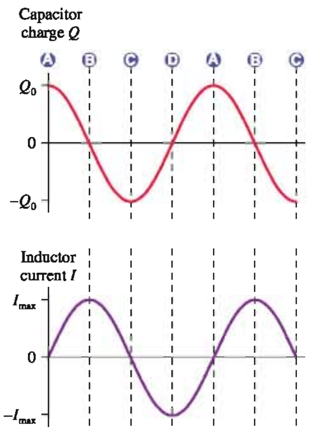
As the capacitor charge oscillates, so does the current through the inductor. Using Equation 34.45 gives the current through the inductor:

$$I = -\frac{dQ}{dt} = \omega Q_0\sin\omega t = I_{max}\sin\omega t \tag{34.52}$$

where $I_{max} = \omega Q_0$ is the maximum current.

An *LC* circuit is an *electric oscillator*, oscillating at frequency $f = \omega/2\pi$. **FIGURE 34.46** shows graphs of the capacitor charge Q and the inductor current I as functions of time. The letters over the graph match the labels in Figure 34.45, and you should compare the two. Notice that Q and I are 90° out of phase. The current is zero when the capacitor is fully charged, as expected, and the charge is zero when the current is maximum.

FIGURE 34.46 The oscillations of an *LC* circuit.



EXAMPLE 34.15 An AM radio oscillator

You have a 1.0 mH inductor. What capacitor should you choose to make an oscillator with a frequency of 920 kHz? (This frequency is near the center of the AM radio band.)

SOLVE The angular frequency is $\omega = 2\pi f = 5.78 \times 10^6$ rad/s. Using Equation 34.51 for ω gives the required capacitor:

$$C = \frac{1}{\omega^2 L} = \frac{1}{(5.78 \times 10^6 \text{ rad/s})^2(0.0010 \text{ H})}$$
$$= 3.0 \times 10^{-11} \text{ F} = 30 \text{ pF}$$

An *LC* circuit, like a mass on a spring, wants to respond only at its natural oscillation frequency $\omega = 1/\sqrt{LC}$. In Chapter 14 we defined a strong response at the natural frequency as a *resonance*, and resonance is the basis for all telecommunications. The input circuit in radios, televisions, and cell phones is an *LC* circuit driven by the signal picked up by the antenna. This signal is the superposition of hundreds of sinusoidal waves at different frequencies, one from each transmitter in the area, but the circuit responds only to the *one* signal that matches the circuit's natural frequency. That particular signal generates a large-amplitude current that can be further amplified and decoded to become the output that you hear.

Turning the dial on your radio or television changes a *variable capacitor*, thus changing the resonance frequency so that you pick up a different station. Cell phones are a bit more complicated. You don't change the capacitance yourself, but a "smart" circuit inside can change its capacitance in response to command signals it receives from the transmitter. The result is the same. Your cell phone responds to the one signal being broadcast to you and ignores the hundreds of other signals that are being broadcast simultaneously at different frequencies.

34.10 *LR* Circuits

14.1 Activ Online Physics

A circuit consisting of an inductor, a resistor, and (perhaps) a battery is called an ***LR* circuit.** FIGURE 34.47a is an example of an *LR* circuit. We'll assume that the switch has been in position a for such a long time that the current is steady and unchanging. There's no potential difference across the inductor, because $dI/dt = 0$, so it simply acts like a piece of wire. The current flowing around the circuit is determined entirely by the battery and the resistor: $I_0 = \Delta V_{bat}/R$.

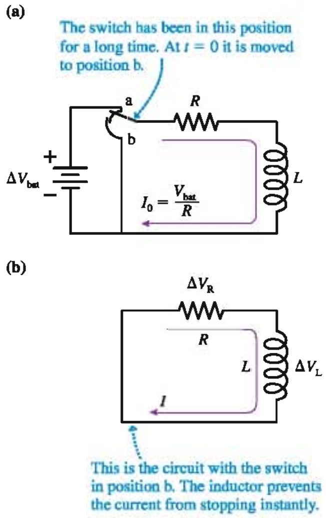


FIGURE 34.47 An *LR* circuit.

NOTE ▶ It's important not to open switches in inductor circuits because they'll spark, as Figure 34.43 showed. The unusual switch in Figure 34.47 is designed to make the new contact just before breaking the old one. Thus, there's never an open circuit across the switch. ◀

What happens if, at $t = 0$, the switch is suddenly moved to position b? With the battery no longer in the circuit, you might expect the current to stop immediately. But the inductor won't let that happen. The current will continue for some period of time as the inductor's magnetic field drops to zero. In essence, the energy stored in the inductor allows it to act like a battery for a short period of time. Our goal is to determine how the current decays after the switch is moved.

FIGURE 34.47b shows the circuit after the switch is changed. Our starting point, once again, is Kirchhoff's voltage law. The potential differences around a closed loop must sum to zero. For this circuit, Kirchhoff's law is

$$\Delta V_R + \Delta V_L = 0 \tag{34.53}$$

The potential differences in the direction of the current are $\Delta V_R = -IR$ for the resistor and $\Delta V_L = -L(dI/dt)$ for the inductor. Substituting these into Equation 34.53 gives

$$-RI - L\frac{dI}{dt} = 0 \tag{34.54}$$

We're going to need to integrate to find the current I as a function of time. Before doing so, rearrange Equation 34.54 to get all the current terms on one side of the equation and all the time terms on the other:

$$\frac{dI}{I} = -\frac{R}{L}dt = -\frac{dt}{(L/R)} \tag{34.55}$$

We know that the current at $t = 0$, when the switch was moved, was I_0. We want to integrate from these starting conditions to current I at the unspecified time t. That is,

$$\int_{I_0}^{I}\frac{dI}{I} = -\frac{1}{(L/R)}\int_0^t dt \tag{34.56}$$

Both are common integrals, giving

$$\ln I\Big|_{I_0}^{I} = \ln I - \ln I_0 = \ln\left(\frac{I}{I_0}\right) = -\frac{t}{(L/R)} \tag{34.57}$$

We can solve for the current I by taking the exponential of both sides, then multiplying by I_0. Doing so gives I, the current as a function of time:

$$I = I_0 e^{-t/(L/R)} \tag{34.58}$$

Notice that $I = I_0$ at $t = 0$, as expected.

The argument of the exponential function must be dimensionless, so L/R must have dimensions of time. If we define the **time constant** τ of the *LR* circuit to be

$$\tau = \frac{L}{R} \tag{34.59}$$

then we can write Equation 34.58 as

$$I = I_0 e^{-t/\tau} \qquad (34.60)$$

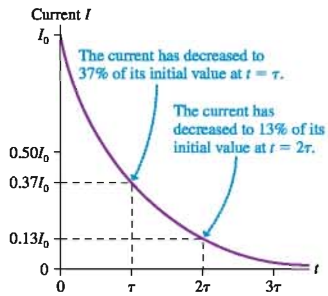
The time constant is the time at which the current has decreased to e^{-1} (about 37%) of its initial value. We can see this by computing the current at the time $t = \tau$.

$$I(\text{at } t = \tau) = I_0 e^{-\tau/\tau} = e^{-1} I_0 = 0.37 I_0 \qquad (34.61)$$

Thus the time constant for an *LR* circuit functions in exactly the same way as the time constant for the *RC* circuit we analyzed in Chapter 32. At time $t = 2\tau$, the current has decreased to $e^{-2} I_0$, or about 13% of its initial value.

The current is graphed in **FIGURE 34.48**. You can see that the current decays exponentially. The *shape* of the graph is always the same, regardless of the specific value of the time constant τ.

FIGURE 34.48 The current decay in an *LR* circuit.



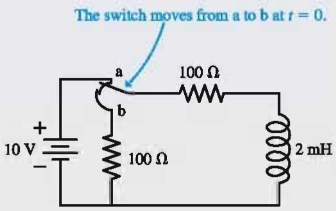
EXAMPLE 34.16 Exponential decay in an *LR* circuit

The switch in **FIGURE 34.49** has been in position a for a long time. It is changed to position b at $t = 0$ s.

a. What is the current in the circuit at $t = 5.0\ \mu s$?

b. At what time has the current decayed to 1% of its initial value?

FIGURE 34.49 The *LR* circuit of Example 34.16.



MODEL This is an *LR* circuit. We'll assume ideal wires and an ideal inductor.

VISUALIZE The two resistors will be in series after the switch is thrown.

SOLVE Before the switch is thrown, while $\Delta V_L = 0$, the current is $I_0 = (10\text{ V})/(100\ \Omega) = 0.10\text{ A} = 100\text{ mA}$. This will be the initial current after the switch is thrown because the current through an inductor can't change instantaneously. The circuit resistance after the switch is thrown is $R = 200\ \Omega$, so the time constant is

$$\tau = \frac{L}{R} = \frac{2.0 \times 10^{-3}\text{ H}}{200\ \Omega} = 1.0 \times 10^{-5}\text{ s} = 10\ \mu\text{s}$$

a. The current at $t = 5.0\ \mu s$ is

$$I = I_0 e^{-t/\tau} = (100\text{ mA})e^{-(5.0\,\mu\text{s})/(10\,\mu\text{s})} = 61\text{ mA}$$

b. To find the time at which a particular current is reached we need to go back to Equation 34.57 and solve for t:

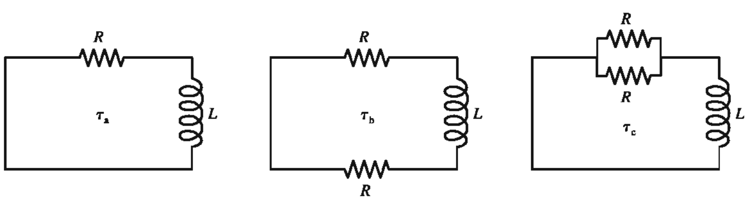
$$t = -\frac{L}{R}\ln\left(\frac{I}{I_0}\right) = -\tau\ln\left(\frac{I}{I_0}\right)$$

The time at which the current has decayed to 1 mA (1% of I_0) is

$$t = -(10\ \mu\text{s})\ln\left(\frac{1\text{ mA}}{100\text{ mA}}\right) = 46\ \mu\text{s}$$

ASSESS For all practical purposes, the current has decayed away in $\approx 50\ \mu s$. The inductance in this circuit is not large, so a short decay time is not surprising.

STOP TO THINK 34.7 Rank in order, from largest to smallest, the time constants τ_a, τ_b, and τ_c of these three circuits.



SUMMARY

The goal of Chapter 34 has been to understand and apply electromagnetic induction.

General Principles

Faraday's Law

MODEL Make simplifying assumptions.

VISUALIZE Use Lenz's law to determine the direction of the **induced current.**

SOLVE The **induced emf** is

$$\mathcal{E} = \left|\frac{d\Phi_m}{dt}\right|$$

Multiply by N for an N-turn coil.
The size of the induced current is $I = \mathcal{E}/R$.

ASSESS Is the result reasonable?

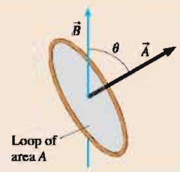
Lenz's Law

There is an induced current in a closed conducting loop if and only if the magnetic flux through the loop is changing.
The direction of the induced current is such that the induced magnetic field opposes the *change* in the flux.

Magnetic flux

Magnetic flux measures the amount of magnetic field passing through a surface.

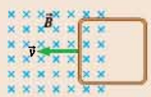
$$\Phi_m = \vec{A}\cdot\vec{B} = AB\cos\theta$$



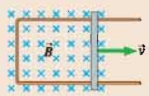
Important Concepts

Three ways to change the flux

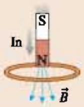
1. A loop moves into or out of a magnetic field.



2. The loop changes area or rotates.

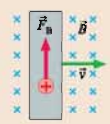


3. The magnetic field through the loop increases or decreases.

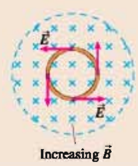


Two ways to create an induced current

1. A **motional emf** due to magnetic forces on moving charge carriers.



2. An induced electric field due to a changing magnetic field.



Applications

Inductors

Solenoid inductance $L_{solenoid} = \dfrac{\mu_0 N^2 A}{l}$

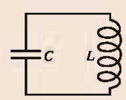
Potential difference $\Delta V_L = -L\dfrac{dI}{dt}$

Energy stored $U_L = \frac{1}{2}LI^2$

Magnetic energy density $u_B = \dfrac{1}{2\mu_0}B^2$

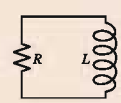
LC circuit

Oscillates at $\omega = \sqrt{\dfrac{1}{LC}}$



LR circuit

Exponential change with $\tau = \dfrac{L}{R}$



Terms and Notation

electromagnetic induction	area vector, $\vec{A}$	induced magnetic field	inductor

CONCEPTUAL QUESTIONS

1. What is the direction of the induced current in FIGURE Q34.1?

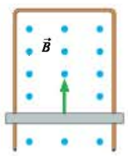

FIGURE Q34.1

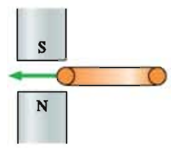

FIGURE Q34.2

2. You want to insert a loop of copper wire between the two permanent magnets in FIGURE Q34.2. Is there an attractive magnetic force that tends to *pull* the loop in, like a magnet pulls on a paper clip? Or do you need to *push* the loop in against a repulsive force? Explain.

3. A vertical, rectangular loop of copper wire is half in and half out of the horizontal magnetic field in FIGURE Q34.3. (The field is zero beneath the dotted line.) The loop is released and starts to fall. Is there a net magnetic force on the loop? If so, in which direction? Explain.

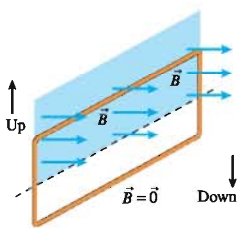

FIGURE Q34.3

4. FIGURE Q34.4 shows four different circular loops that are perpendicular to the page. The radius of loops c and d is twice that of loops a and b. The magnetic field is the same for each. Rank in order, from largest to smallest, the magnetic fluxes Φ_a to Φ_d. Some may be equal. Explain.

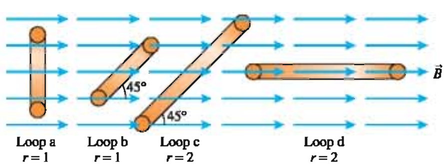

FIGURE Q34.4

5. Does the loop of wire in FIGURE Q34.5 have a clockwise current, a counterclockwise current, or no current under the following circumstances? Explain.
   a. The magnetic field points out of the page and is increasing.
   b. The magnetic field points out of the page and is constant.
   c. The magnetic field points out of the page and is decreasing.

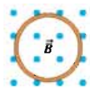

FIGURE Q34.5

FIGURE Q34.6

6. The two loops of wire in FIGURE Q34.6 are stacked one above the other. Does the upper loop have a clockwise current, a counterclockwise current, or no current at the following times? Explain.
   a. Before the switch is closed.
   b. Immediately after the switch is closed.
   c. Long after the switch is closed.
   d. Immediately after the switch is reopened.

7. FIGURE Q34.7 shows a bar magnet being pushed toward a conducting loop from below, along the axis of the loop.
   a. What is the current direction in the loop? Explain.
   b. Is there a magnetic force on the loop? If so, in which direction? Explain.

   Hint: A current loop is a magnetic dipole.

   c. Is there a force on the magnet? If so, in which direction?

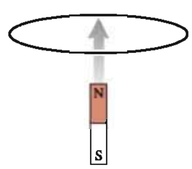

FIGURE Q34.7

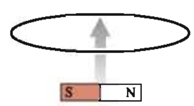

FIGURE Q34.8

8. A bar magnet is pushed toward a loop of wire as shown in FIGURE Q34.8. Is there a current in the loop? If so, in which direction? If not, why not?

9. FIGURE Q34.9 shows a bar magnet, a coil of wire, and a current meter. Is the current through the meter right to left, left to right, or zero for the following circumstances? Explain.
   a. The magnet is inserted into the coil.
   b. The magnet is held at rest inside the coil.
   c. The magnet is withdrawn from the coil.

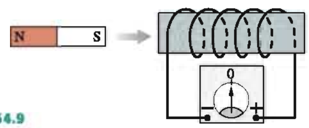

FIGURE Q34.9

10. FIGURE Q34.10 shows two coils of wire, a switch, and a current meter. Is the current through the meter right to left, left to right, or zero for the following circumstances? Explain.
    a. Just after the switch on the left coil is closed.
    b. Long after the switch on the left coil is closed.
    c. Just after the switch on the left coil is reopened.

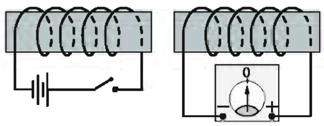

FIGURE Q34.10

11. Is the magnetic field strength in FIGURE Q34.11 increasing, decreasing, or steady? Explain.

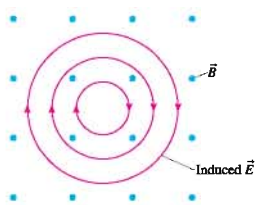

FIGURE Q34.11

12. a. Can you tell which of the inductors in FIGURE Q34.12 has the larger current through it? If so, which one? Explain.
    b. Can you tell through which inductor the current is changing more rapidly? If so, which one? Explain
    c. If the current enters the inductor from the bottom, can you tell if the current is increasing, decreasing, or staying the same? If so, which? Explain.

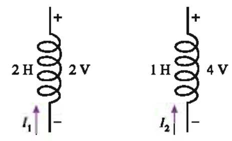

FIGURE Q34.12

13. An inductor with a 2.0 A current stores energy. At what current will the stored energy be twice as large?
14. An LC circuit oscillates at a frequency of 2000 Hz. What will the frequency be if the inductance is quadrupled?
15. Rank in order, from largest to smallest, the three time constants τ_a to τ_c for the three circuits in FIGURE Q34.15. Explain.

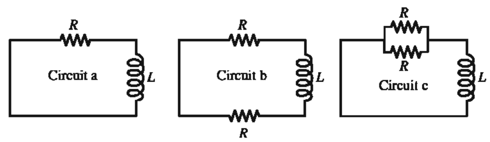

FIGURE Q34.15

16. For the circuit of FIGURE Q34.16:
    a. What is the battery current immediately after the switch closes? Explain.
    b. What is the battery current after the switch has been closed a long time? Explain.

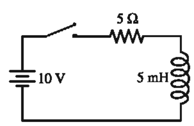

FIGURE Q34.16

EXERCISES AND PROBLEMS

Exercises

Section 34.2 Motional emf

1. | The earth's magnetic field strength is 5.0×10^{-5} T. How fast would you have to drive your car to create a 1.0 V motional emf along your 1.0-m-long radio antenna? Assume that the motion of the antenna is perpendicular to $\vec{B}$.
2. | A potential difference of 0.050 V is developed across a 10-cm-long wire as it moves through a magnetic field at 5.0 m/s. The magnetic field is perpendicular to the axis of the wire. What are the direction and strength of the magnetic field?

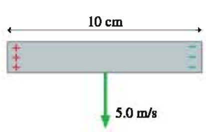

FIGURE EX34.2

3. | A 10-cm-long wire is pulled along a U-shaped conducting rail in a perpendicular magnetic field. The total resistance of the wire and rail is 0.20 Ω. Pulling the wire with a force of 1.0 N causes 4.0 W of power to be dissipated in the circuit.
   a. What is the speed of the wire when pulled with 1.0 N?
   b. What is the strength of the magnetic field?

Section 34.3 Magnetic Flux

4. | What is the magnetic flux through the loop shown in FIGURE EX34.4?

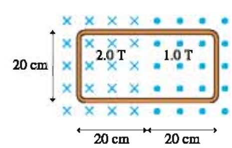

FIGURE EX34.4

5. || A 2.0-cm-diameter solenoid passes through the center of a 6.0-cm-diameter loop. The magnetic field inside the solenoid is 0.20 T. What is the magnetic flux through the loop when it is perpendicular to the solenoid and when it is tilted at a 60° angle?

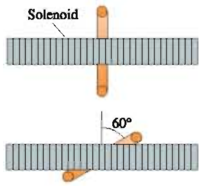

FIGURE EX34.5

6. | What is the magnetic flux through the loop shown in FIGURE EX34.6?

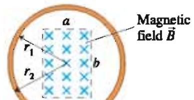

FIGURE EX34.6

Section 34.4 Lenz's Law

7. | There is a ccw induced current in the conducting loop shown in FIGURE EX34.7. Is the magnetic field inside the loop increasing in strength, decreasing in strength, or steady?

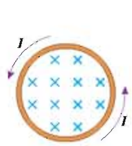

FIGURE EX34.7

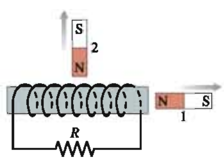

FIGURE EX34.8

8. | A solenoid is wound as shown in FIGURE EX34.8.
   a. Is there an induced current as magnet 1 is moved away from the solenoid? If so, what is the current direction through resistor R?
   b. Is there an induced current as magnet 2 is moved away from the solenoid? If so, what is the current direction through resistor R?

9. || The current in the solenoid of FIGURE EX34.9 is increasing. The solenoid is surrounded by a conducting loop. Is there a current in the loop? If so, is the loop current cw or ccw?

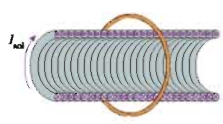

FIGURE EX34.9

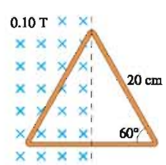

FIGURE EX34.10

10. | The metal equilateral triangle in FIGURE EX34.10, 20 cm on each side, is halfway into a 0.10 T magnetic field.
   a. What is the magnetic flux through the triangle?
   b. If the magnetic field strength decreases, what is the direction of the induced current in the triangle?

Section 34.5 Faraday's Law

11. | FIGURE EX34.11 shows a 10-cm-diameter loop in three different magnetic fields. The loop's resistance is 0.20 Ω. For each case, determine the induced emf, the induced current, and the direction of the current.

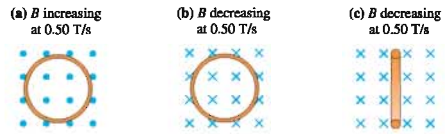

FIGURE EX34.11

12. | The loop in FIGURE EX34.12 is being pushed into the 0.20 T magnetic field at 50 m/s. The resistance of the loop is 0.10 Ω. What are the direction and the magnitude of the current in the loop?

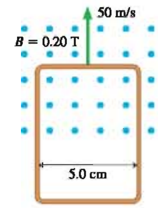

FIGURE EX34.12

13. || A 1000-turn coil of wire 2.0 cm in diameter is in a magnetic field that drops from 0.10 T to 0 T in 10 ms. The axis of the coil is parallel to the field. What is the emf of the coil?

14. | The resistance of the loop in FIGURE EX34.14 is 0.20 Ω. Is the magnetic field strength increasing or decreasing? At what rate (T/s)?

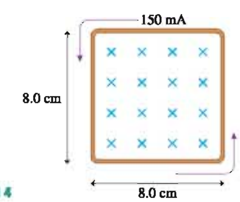

FIGURE EX34.14

Section 34.6 Induced Fields

15. || FIGURE EX34.15 shows the current as a function of time through a 20-cm-long, 4.0-cm-diameter solenoid with 400 turns. Draw a graph of the induced electric field strength as a function of time at a point 1.0 cm from the axis of the solenoid.

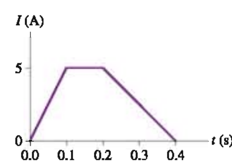

FIGURE EX34.15

16. || The magnetic field inside a 5.0-cm-diameter solenoid is 2.0 T and decreasing at 4.0 T/s. What is the electric field strength inside the solenoid at point (a) on the axis and (b) 2.0 cm from the axis?

17. | The magnetic field in FIGURE EX34.17 is decreasing at the rate 0.10 T/s. What is the acceleration (magnitude and direction) of a proton at rest at points a to d?

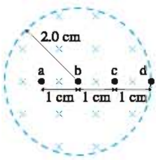

FIGURE EX34.17

Section 34.8 Inductors

18. | What is the potential difference across a 10 mH inductor if the current through the inductor drops from 150 mA to 50 mA in 10 μs? What is the direction of this potential difference? That is, does the potential increase or decrease along the direction of the current?
19. | The maximum allowable potential difference across a 200 mH inductor is 400 V. You need to raise the current through the inductor from 1.0 A to 3.0 A. What is the minimum time you should allow for changing the current?
20. | A 100 mH inductor whose windings have a resistance of 4.0 Ω is connected across a 12 V battery having an internal resistance of 2.0 Ω. How much energy is stored in the inductor?
21. || How much energy is stored in a 3.0-cm-diameter, 12-cm-long solenoid that has 200 turns of wire and carries a current of 0.80 A?

Section 34.9 *LC* Circuits

22. || An FM radio station broadcasts at a frequency of 100 MHz. What inductance should be paired with a 10 pF capacitor to build a receiver circuit for this station?
23. || A 2.0 mH inductor is connected in parallel with a variable capacitor. The capacitor can be varied from 100 pF to 200 pF. What is the range of oscillation frequencies for this circuit?
24. || An electric oscillator is made with a 0.10 μF capacitor and a 1.0 mH inductor. The capacitor is initially charged to 5.0 V. What is the maximum current through the inductor as the circuit oscillates?

Section 34.10 *LR* Circuits

25. | What value of resistor R gives the circuit in FIGURE EX34.25 a time constant of 10 μs?

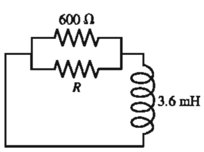

FIGURE EX34.25

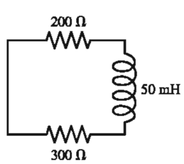

FIGURE EX34.26

26. | At $t = 0$ s, the current in the circuit in FIGURE EX34.26 is I_0. At what time is the current $\frac{1}{2}I_0$?

Problems

27. || FIGURE P34.27 shows a 10 cm $\times$ 10 cm square bent at a 90° angle. A uniform 0.050 T magnetic field points downward at a 45° angle. What is the magnetic flux through the loop?

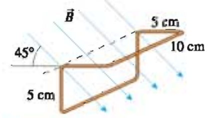

FIGURE P34.27

28. || A 5.0-cm-diameter coil has 20 turns and a resistance of 0.50 Ω. A magnetic field perpendicular to the coil is $B = 0.020t + 0.010t^2$, where B is in tesla and t is in seconds.
    a. Draw a graph of B as a function of time from $t = 0$ s to $t = 10$ s.
    b. Find an expression for the induced current $I(t)$ as a function of time.
    c. Evaluate I at $t = 5$ s and $t = 10$ s.
29. || A 20 cm $\times$ 20 cm square loop has a resistance of 0.10 Ω. A magnetic field perpendicular to the loop is $B = 4t - 2t^2$, where B is in tesla and t is in seconds.
    a. Determine B, $\mathcal{E}$, and I at half-second intervals from 0 s to 2 s.
    b. Use your results of part a to draw graphs of B and I versus time.
30. || A 100-turn, 4.0-cm-diameter coil has a resistance of 1.0 Ω. A magnetic field perpendicular to the coil is $B = t - \frac{1}{4}t^2$, where B is in tesla and t is in seconds.
    a. Draw a graph of B as a function of time from $t = 0$ s to $t = 4$ s.
    b. Find an expression for the induced current $I(t)$ as a function of time.
    c. Evaluate I at $t = 1$, 2, and 3 s.
31. || A 25-turn, 10-cm-diameter coil is oriented in a vertical plane with its axis aligned east-west. A magnetic field pointing to the northeast decreases from 0.80 T to 0.20 T in 2.0 s. What is the emf induced in the coil?
32. || A 100-turn, 2.0-cm-diameter coil is at rest in a horizontal plane. A uniform magnetic field 60° away from vertical increases from 0.50 T to 1.50 T in 0.60 s. What is the induced emf in the coil?
33. || A 100-turn, 8.0-cm-diameter coil is made of 0.50-mm-diameter copper wire. A magnetic field is perpendicular to the coil. At what rate must B increase to induce a 2.0 A current in the coil?
34. || A circular loop made from a flexible, conducting wire is shrinking. Its radius as a function of time is $r = r_0e^{-\beta t}$. The loop is perpendicular to a steady, uniform magnetic field B. Find an expression for the induced emf in the loop at time t.
35. || A 10 cm $\times$ 10 cm square loop lies in the xy-plane. The magnetic field in this region of space is $B = (0.30t\hat{\imath} + 0.50t^2\hat{k})$ T, where t is in s. What is the emf induced in the loop at (a) $t = 0.5$ s and (b) $t = 1.0$ s?
36. ||| A 20 cm $\times$ 20 cm square loop of wire lies in the xy-plane with its bottom edge on the x-axis. The resistance of the loop is 0.50 Ω. A magnetic field parallel to the z-axis is given by $B = 0.80y^2t$, where B is in tesla, y in meters, and t in seconds. What is the size of the induced current in the loop at $t = 0.50$ s?
37. ||| A 2.0 cm $\times$ 2.0 cm square loop of wire with resistance 0.010 Ω has one edge parallel to a long straight wire. The near edge of the loop is 1.0 cm from the wire. The current in the wire is increasing at the rate of 100 A/s. What is the current in the loop?

38. ||| The rectangular loop in FIGURE P34.38 has 0.020 Ω resistance. What is the induced current in the loop at this instant?

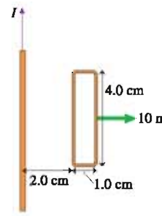

FIGURE P34.38

39. || A 4.0-cm-diameter loop with resistance 0.10 Ω surrounds a 2.0-cm-diameter solenoid. The solenoid is 10 cm long, has 100 turns, and carries the current shown in the graph. A positive current is cw when seen from the left. Determine the current in the loop at (a) $t = 0.5$ s, (b) $t = 1.5$ s, and (c) $t = 2.5$ s.

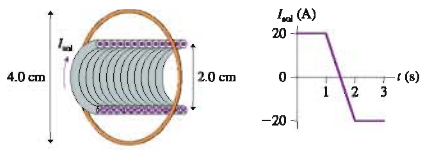

FIGURE P34.39

40. || FIGURE P34.40 shows a five-turn, 1.0-cm-diameter coil with $R = 0.10\ \Omega$ inside a 2.0-cm-diameter solenoid. The solenoid is 8.0 cm long, has 120 turns, and carries the current shown in the graph. A positive current is cw when seen from the left. Determine the current in the coil at $t = 0.010$ s.

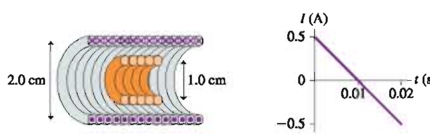

FIGURE P34.40

41. || FIGURE P34.41 shows two 20-turn coils tightly wrapped on the same 2.0-cm-diameter cylinder with 1.0-mm-diameter wire. The current through coil 1 is shown in the graph. Determine the current in coil 2 at (a) $t = 0.05$ s and (b) $t = 0.25$ s. A positive current is into the page at the top of a loop. Assume that the magnetic field of coil 1 passes entirely through coil 2.

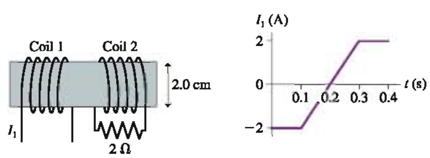

FIGURE P34.41

42. ||| A 50-turn, 4.0-cm-diameter coil with $R = 0.50\ \Omega$ surrounds a 2.0-cm-diameter solenoid. The solenoid is 20 cm long and has 200 turns. The 60 Hz current through the solenoid is $I_{sol} = (0.50\ \text{A})\sin(2\pi ft)$. Find an expression for I_{coil}, the induced current in the coil as a function of time.

43. || A loop antenna, such as is used on a television to pick up UHF broadcasts, is 25 cm in diameter. The plane of the loop is perpendicular to the oscillating magnetic field of a 150 MHz electromagnetic wave. The magnetic field through the loop is $B = (20\ \text{nT})\sin\omega t$.
   a. What is the maximum emf induced in the antenna?
   b. What is the maximum emf if the loop is turned 90° to be perpendicular to the oscillating electric field?

44. || A 40-turn, 4.0-cm-diameter coil with $R = 0.40\ \Omega$ surrounds a 3.0-cm-diameter solenoid. The solenoid is 20 cm long and has 200 turns. The 60 Hz current through the solenoid is $I = I_0\sin(2\pi ft)$. What is I_0 if the maximum induced current in the coil is 0.20 A?

45. || Electricity is distributed from electrical substations to neighborhoods at 15,000 V. This is a 60 Hz oscillating (AC) voltage. Neighborhood transformers, seen on utility poles, step this voltage down to the 120 V that is delivered to your house.
   a. How many turns does the primary coil on the transformer have if the secondary coil has 100 turns?
   b. No energy is lost in an ideal transformer, so the output power P_{out} from the secondary coil equals the input power P_{in} to the primary coil. Suppose a neighborhood transformer delivers 250 A at 120 V. What is the current in the 15,000 V line from the substation?

46. ||| A small, 2.0-mm-diameter circular loop with $R = 0.020\ \Omega$ is at the center of a large 100-mm-diameter circular loop. Both loops lie in the same plane. The current in the outer loop changes from +1.0 A to −1.0 A in 0.10 s. What is the induced current in the inner loop?

47. ||| The square loop shown in FIGURE P34.47 moves into a 0.80 T magnetic field at a constant speed of 10 m/s. The loop has a resistance of 0.10 Ω, and it enters the field at $t = 0$ s.

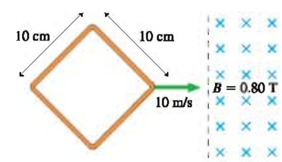

FIGURE P34.47

   a. Find the induced current in the loop as a function of time. Give your answer as a graph of I versus t from $t = 0$ s to $t = 0.020$ s.
   b. What is the maximum current? What is the position of the loop when the current is maximum?

48. || A 4.0-cm-long slide wire moves outward with a speed of 100 m/s in a 1.0 T magnetic field. (See Figure 34.27.) At the instant the circuit forms a 4.0 cm × 4.0 cm square, with $R = 0.010\ \Omega$ on each side, what are
   a. The induced emf?
   b. The induced current?
   c. The potential difference between the two ends of the moving wire?

49. || A 20-cm-long, zero-resistance slide wire moves outward, on zero-resistance rails, at a steady speed of 10 m/s in a 0.10 T magnetic field. (See Figure 34.27.) On the opposite side, a 1.0 Ω carbon resistor completes the circuit by connecting the two rails. The mass of the resistor is 50 mg.
   a. What is the induced current in the circuit?
   b. How much force is needed to pull the wire at this speed?
   c. If the wire is pulled for 10 s, what is the temperature increase of the carbon? The specific heat of carbon is 710 J/kg C°.

50. | The 10-cm-wide, zero-resistance slide wire shown in FIGURE P34.50 is pushed toward the 2.0 Ω resistor at a steady speed of 0.50 m/s. The magnetic field strength is 0.50 T.
   a. How big is the pushing force?
   b. How much power does the pushing force supply to the wire?
   c. What are the direction and magnitude of the induced current?
   d. How much power is dissipated in the resistor?

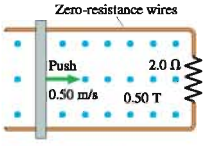

FIGURE P34.50

51. || Your camping buddy has an idea for a light to go inside your tent. He happens to have a powerful (and heavy!) horseshoe magnet that he bought at a surplus store. This magnet creates a 0.20 T field between two pole tips 10 cm apart. His idea is to build a hand-cranked generator with a rotating 5.0-cm-radius semicircle between the pole tips. He thinks you can make enough current to fully light a 1.0 Ω lightbulb rated at 4.0 W. That's not super bright, but it should be plenty of light for routine activities in the tent.
   a. Find an expression for the induced current as a function of time if you turn the crank at frequency f. Assume that the semicircle is at its highest point at $t = 0$ s.
   b. With what frequency will you have to turn the crank for the maximum current to fully light the bulb? Is this feasible?

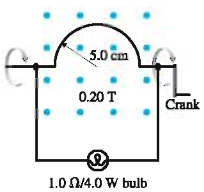

FIGURE P34.51

52. || You've decided to make a magnetic projectile launcher for your science project. An aluminum bar of length l slides along metal rails through a magnetic field B. The switch closes at $t = 0$ s, while the bar is at rest, and a battery of emf $\mathcal{E}_{bat}$ starts a current flowing around the loop. The battery has internal resistance r. The resistance of the rails and the bar are effectively zero.
   a. Show that the bar reaches a terminal speed v_{term}, and find an expression for v_{term}.
   b. Evaluate v_{term} for $\mathcal{E}_{bat} = 1.0$ V, $r = 0.10\ \Omega$, $l = 6.0$ cm, and $B = 0.50$ T.

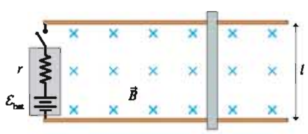

FIGURE P34.52

53. ||| A slide wire of length l, mass m, and resistance R slides down a U-shaped metal track that is tilted upward at angle θ. The track has zero resistance and no friction. A vertical magnetic field B fills the loop formed by the track and the slide wire.
   a. Find an expression for the induced current I when the slide wire moves at speed v.
   b. Show that the slide wire reaches a terminal speed v_{term}, and find an expression for v_{term}.

54. ||| FIGURE P34.54 shows a U-shaped conducting rail that is oriented vertically in a horizontal magnetic field. The rail has no electric resistance and does not move. A slide wire with mass m and resistance R can slide up and down without friction while maintaining electrical contact with the rail. The slide wire is released from rest.
   a. Show that the slide wire reaches a terminal speed v_{term}, and find an expression for v_{term}.
   b. Determine the value of v_{term} if $l = 20$ cm, $m = 10$ g, $R = 0.10\ \Omega$, and $B = 0.50$ T.

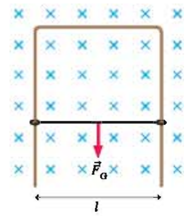

FIGURE P34.54

55. || Experiments to study vision often need to track the movements of a subject's eye. One way of doing so is to have the subject sit in a magnetic field while wearing special contact lenses with a coil of very fine wire circling the edge. A current is induced in the coil each time the subject rotates his eye. Consider an experiment in which a 20-turn, 6.0-mm-diameter coil of wire circles the subject's cornea while a 1.0 T magnetic field is directed as shown. The subject begins by looking straight ahead. What emf is induced in the coil if the subject shifts his gaze by 5° in 0.20 s?

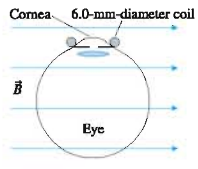

FIGURE P34.55

56. || A 10-turn coil of wire having a diameter of 1.0 cm and a resistance of 0.20 Ω is in a 1.0 mT magnetic field, with the coil oriented for maximum flux. The coil is connected to an uncharged 1.0 μF capacitor rather than to a current meter. The coil is quickly pulled out of the magnetic field. Afterward, what is the voltage across the capacitor?
   Hint: Use $I = dq/dt$ to relate the *net* change of flux to the amount of charge that flows to the capacitor.

57. ||| The magnetic field at one place on the earth's surface is 55 μT in strength and tilted 60° down from horizontal. A 200-turn coil having a diameter of 4.0 cm and a resistance of 2.0 Ω is connected to a 1.0 μF capacitor rather than to a current meter. The coil is held in a horizontal plane and the capacitor is discharged. Then the coil is quickly rotated 180° so that the side that had been facing up is now facing down. Afterward, what is the voltage across the capacitor? See the Hint in Problem 56.

58. || The magnetic field inside a 4.0-cm-diameter superconducting solenoid varies sinusoidally between 8.0 T and 12.0 T at a frequency of 10 Hz.
   a. What is the maximum electric field strength at a point 1.5 cm from the solenoid axis?
   b. What is the value of B at the instant E reaches its maximum value?

59. || Equation 34.26 is an expression for the induced electric field inside a solenoid ($r < R$). Find an expression for the induced electric field outside a solenoid ($r > R$) in which the magnetic field is changing at the rate dB/dt.

60. || A 2.0-cm-diameter solenoid is wrapped with 1000 turns per meter. 0.50 cm from the axis, the strength of an induced electric field is 5.0×10^{-4} V/m. What is the rate dI/dt with which the current through the solenoid is changing?

61. || A solenoid inductor has an emf of 0.20 V when the current through it changes at the rate 10.0 A/s. A steady current of 0.10 A produces a flux of 5.0 μWb per turn. How many turns does the inductor have?

62. ||| A solenoid inductor carries a current of 200 mA. It has a magnetic flux of 20 μWb per turn and stores 1.0 mJ of energy. How many turns does the inductor have?

63. ||| You need to make a 100 μH inductor on a cylinder that is 5.0 cm long and 1.0 cm in diameter. You plan to wrap four layers of wire around the cylinder. What diameter wire should you use if the coils are tightly wound with no space between them? The wire diameter is small enough you don't need to consider the change in the coil's diameter for the outer layers.

64. a. What is the magnetic energy density at the center of a 4.0-cm-diameter loop carrying a current of 1.0 A?
b. What current in a straight wire gives the magnetic energy density you found in part a at a point 2.0 cm from the wire?

65. || MRI (magnetic resonance imaging) is a medical technique that produces detailed "pictures" of the interior of the body. The patient is placed into a solenoid that is 40 cm in diameter and 1.0 m long. A 100 A current creates a 5.0 T magnetic field inside the solenoid. To carry such a large current, the solenoid wires are cooled with liquid helium until they become superconducting (no electric resistance).
a. How much magnetic energy is stored in the solenoid? Assume that the magnetic field is uniform within the solenoid and quickly drops to zero outside the solenoid.
b. How many turns of wire does the solenoid have?

66. | One possible concern with MRI (see Problem 65) is turning the magnetic field on or off too quickly. Bodily fluids are conductors, and a changing magnetic field could cause electric currents to flow through the patient. Suppose a typical patient has a maximum cross-section area of 0.060 m^2. What is the smallest time interval in which a 5.0 T magnetic field can be turned on or off if the induced emf around the patient's body must be kept to less than 0.10 V?

67. || FIGURE P34.67 shows the current through a 10 mH inductor. Draw a graph showing the potential difference ΔV_L across the inductor for these 6 ms.

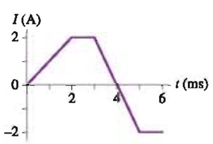

FIGURE P34.67

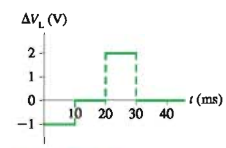

FIGURE P34.68

68. || FIGURE P34.68 shows the potential difference across a 50 mH inductor. The current through the inductor at $t = 0$ s is 0.20 A. Draw a graph showing the current through the inductor from $t = 0$ s to $t = 40$ ms.

69. || The current through inductance L is given by $I = I_0 \sin \omega t$.
a. Find an expression for the potential difference ΔV_L across the inductor.
b. The maximum voltage across the inductor is 0.20 V when $L = 50\ \mu$H and $f = 500$ kHz. What is I_0?

70. || The current through inductance L is given by $I = I_0 e^{-t/\tau}$.
a. Find an expression for the potential difference ΔV_L across the inductor.
b. Evaluate ΔV_L at $t = 0$ s, 1, 2, and 3 ms if $L = 20$ mH, $I_0 = 50$ mA, and $\tau = 1.0$ ms.
c. Draw a graph of ΔV_L versus time from $t = 0$ s to $t = 3$ ms.

71. || An LC circuit is built with a 20 mH inductor and an 8.0 μF capacitor. The current has its maximum value of 0.50 A at $t = 0$ s.
a. How long is it until the capacitor is fully charged?
b. What is the voltage across the capacitor at that time?

72. || An LC circuit has a 10 mH inductor. The current has its maximum value of 0.60 A at $t = 0$ s. A short time later the capacitor reaches its maximum potential difference of 60 V. What is the value of the capacitance?

73. || The maximum charge on the capacitor in an oscillating LC circuit is Q_0. What is the capacitor charge, in terms of Q_0, when the energy in the capacitor's electric field equals the energy in the inductor's magnetic field?

74. || In recent years it has been possible to buy a 1.0 F capacitor. This is an enormously large amount of capacitance. Suppose you want to build a 1.0 Hz oscillator with a 1.0 F capacitor. You have a spool of 0.25-mm-diameter wire and a 4.0-cm-diameter plastic cylinder. How long must your inductor be if you wrap it with 2 layers of closely spaced turns?

75. || For your final exam in electronics, you're asked to build an LC circuit that oscillates at 10 kHz. In addition, the maximum current must be 0.10 A and the maximum energy stored in the capacitor must be 1.0×10^{-5} J. What values of inductance and capacitance must you use?

76. || The switch in FIGURE P34.76 has been in position 1 for a long time. It is changed to position 2 at $t = 0$ s.
a. What is the maximum current through the inductor?
b. What is the first time at which the current is maximum?

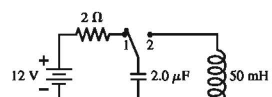

FIGURE P34.76

77. || The 300 μF capacitor in FIGURE P34.77 is initially charged to 100 V, the 1200 μF capacitor is uncharged, and the switches are both open.
a. What is the maximum voltage to which you can charge the 1200 μF capacitor by the proper closing and opening of the two switches?
b. How would you do it? Describe the sequence in which you would close and open switches and the times at which you would do so. The first switch is closed at $t = 0$ s.

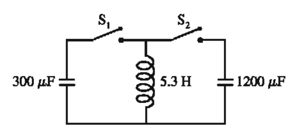

FIGURE P34.77

78. || The switch in FIGURE P34.78 has been open for a long time. It is closed at $t = 0$ s.
a. What is the current through the battery immediately after the switch is closed?
b. What is the current through the battery after the switch has been closed a long time?

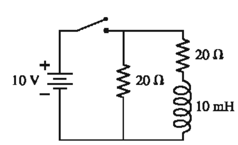

FIGURE P34.78

79. ‖ The switch in FIGURE P34.79 has been open for a long time. It is closed at $t = 0$ s. What is the current through the 20 Ω resistor
a. immediately after the switch is closed?
b. after the switch has been closed a long time?
c. immediately after the switch is reopened?

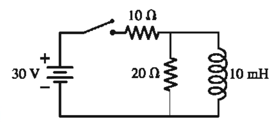

FIGURE P34.79

80. ‖‖ The switch in FIGURE P34.80 has been open for a long time. It is closed at $t = 0$ s.
a. After the switch has been closed for a long time, what is the current in the circuit? Call this current I_0.
b. Find an expression for the current I as a function of time. Write your expression in terms of I_0, R, and L.
c. Sketch a current-versus-time graph from $t = 0$ s until the current is no longer changing.

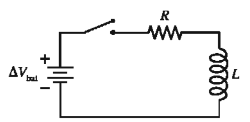

FIGURE P34.80

Challenge Problems

81. The metal wire in FIGURE CP34.81 moves with speed v parallel to a straight wire that is carrying current I. The distance between the two wires is d. Find an expression for the potential difference between the two ends of the moving wire.

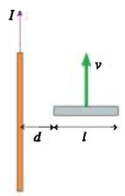

FIGURE CP34.81

82. A rectangular metal loop with 0.050 Ω resistance is placed next to one wire of the RC circuit shown in FIGURE CP34.82. The capacitor is charged to 20 V with the polarity shown, then the switch is closed at $t = 0$ s.
a. What is the direction of current in the loop for $t > 0$ s?
b. What is the current in the loop at $t = 5.0\ \mu$s? Assume that only the circuit wire next to the loop is close enough to produce a significant magnetic field.

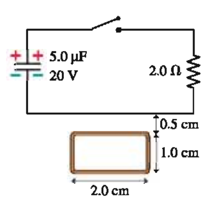

FIGURE CP34.82

83. The L-shaped conductor in FIGURE CP34.83 moves at 10 m/s across a stationary L-shaped conductor in a 0.10 T magnetic field. The two vertices overlap, so that the enclosed area is zero, at $t = 0$ s. The conductor has a resistance of 0.010 ohms *per meter*.
a. What is the direction of the induced current?
b. Find expressions for the induced emf and the induced current as functions of time.
c. Evaluate $\mathcal{E}$ and I at $t = 0.10$ s.

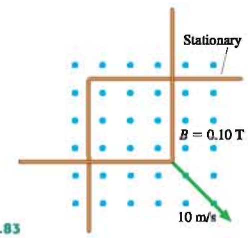

FIGURE CP34.83

84. A closed, square loop is formed with 40 cm of wire having $R = 0.10\ \Omega$, as shown in FIGURE CP34.84. A 0.50 T magnetic field is perpendicular to the loop. At $t = 0$ s, two diagonally opposite corners of the loop begin to move apart at 0.293 m/s.
a. How long does it take the loop to collapse to a straight line?
b. Find an expression for the induced current I as a function of time while the loop is collapsing. Assume that the sides remain straight lines during the collapse.
c. Evaluate I at four or five times during the collapse, then draw a graph of I versus t.

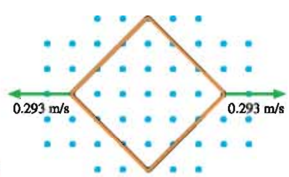

FIGURE CP34.84

85. Let's look at the details of eddy-current braking. A square loop, length l on each side, is shot with velocity v_0 into a uniform magnetic field B. The field is perpendicular to the plane of the loop. The loop has mass m and resistance R, and it enters the field at $t = 0$ s. Assume that the loop is moving to the right along the x-axis and that the field begins at $x = 0$ m.
a. Find an expression for the loop's velocity as a function of time as it enters the magnetic field. You can ignore gravity, and you can assume that the back edge of the loop has not entered the field.
b. Calculate and draw a graph of v over the interval $0\text{ s} \le t \le 0.04$ s for the case that $v_0 = 10$ m/s, $l = 10$ cm, $m = 1.0$ g, $R = 0.0010\ \Omega$, and $B = 0.10$ T. The back edge of the loop does not reach the field during this time interval.

86. An 8.0 cm $\times$ 8.0 cm square loop is halfway into a magnetic field perpendicular to the plane of the loop. The loop's mass is 10 g and its resistance is 0.010 Ω. A switch is closed at $t = 0$ s, causing the magnetic field to increase from 0 to 1.0 T in 0.010 s.
    a. What is the induced current in the square loop?
    b. What is the force on the loop when the magnetic field is 0.50 T? Is the force directed into the magnetic field or away from the magnetic field?
    c. What is the loop's acceleration at $t = 0.005$ s, when the field strength is 0.50 T? If this acceleration stayed constant, how far would the loop move in 0.010 s?
    d. Because 0.50 T is the average field strength, your answer to c is an estimate of how far the loop moves during the 0.010 s in which the field increases to 1.0 T. If your answer is <8 cm, then it is reasonable to neglect the movement of the loop during the 0.010 s that the field ramps up. Is neglecting the movement reasonable?
    e. With what speed is the loop "kicked" away from the magnetic field?

    Hint: What is the impulse on the loop?

87. High-frequency signals are often transmitted along a *coaxial cable*, such as the one shown in FIGURE CP34.87. For example, the cable TV hookup coming into your home is a coaxial cable. The signal is carried on a wire of radius r_1 while the outer conductor of radius r_2 is grounded. A soft, flexible insulating material fills the space between them, and an insulating plastic coating goes around the outside.
    a. Find an expression for the inductance per meter of a coaxial cable. To do so, consider the flux through a rectangle of length l that spans the gap between the inner and outer conductor.
    b. Evaluate the inductance per meter of a cable having $r_1 = 0.50$ mm and $r_2 = 3.0$ mm.

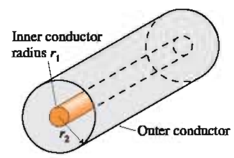

FIGURE CP34.87

STOP TO THINK ANSWERS

Stop to Think 34.1: d. According to the right-hand rule, the magnetic force on a positive charge carrier is to the right.

Stop to Think 34.2: No. The charge carriers in the wire move parallel to $\vec{B}$. There's no magnetic force on a charge moving parallel to a magnetic field.

Stop to Think 34.3: $F_b = F_d > F_a = F_c$. $\vec{F}_a$ is zero because there's no field. $\vec{F}_c$ is also zero because there's no current around the loop. The charge carriers in both the right and left edges are pushed to the bottom of the loop, creating a motional emf but no current. The currents at b and d are in opposite directions, but the forces on the segments in the field are both to the left and of equal magnitude.

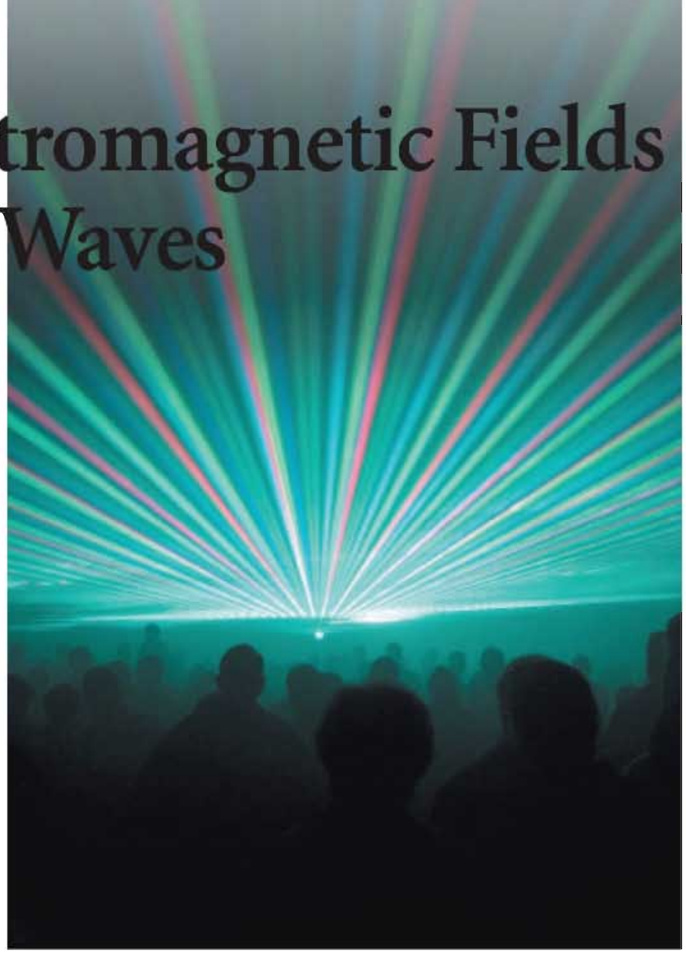
Stop to Think 34.4: Clockwise. The wire's magnetic field as it passes through the loop is into the page. The flux through the loop decreases into the page as the wire moves away. To oppose this decrease, the induced magnetic field needs to point into the page.

Stop to Think 34.5: d. The flux is increasing into the loop. To oppose this increase, the induced magnetic field needs to point out of the page. This requires a ccw induced current. Using the right-hand rule, the magnetic force on the current in the left edge of the loop is to the right, away from the field. The magnetic forces on the top and bottom segments of the loop are in opposite directions and cancel each other.

Stop to Think 34.6: b or **f.** The potential decreases in the direction of increasing current and increases in the direction of decreasing current.

Stop to Think 34.7: $\tau_c > \tau_a > \tau_b$. $\tau = L/R$, so smaller total resistance gives a larger time constant. The parallel resistors have total resistance $R/2$. The series resistors have total resistance $2R$.

35 Electromagnetic Fields and Waves



A laser beam is a subtle interplay of oscillating electric and magnetic fields

▶ Looking Ahead

The goal of Chapter 35 is to study the properties of electromagnetic fields and waves. In this chapter you will learn that:

- The electric field $\vec{E}$ and the magnetic field $\vec{B}$ are *real,* not just convenient fictions.
- The electric field and magnetic field are interdependent. Furthermore, the fields can exist independently of charges and currents.
- The fields obey four general laws, called Maxwell's equations.
- Maxwell's equations predict the existence of electromagnetic waves that travel at speed c, the speed of light.

◀ Looking Back

This chapter will synthesize many ideas about fields and motion. Please review:

- Section 4.4 Relative motion.
- Section 20.3 Sinusoidal traveling waves.
- Sections 28.3 and 28.4 The electric flux and Gauss's law.
- Section 33.6 Ampère's law.
- Sections 34.5 and 34.6 Faraday's law and induced electric fields.

We've now spent nine chapters on electricity and magnetism. You might wonder what more there could be to learn. Surprisingly, there's much more. Our study of the basic properties of charges and currents has been limited mostly to *static* electric and magnetic fields, fields that don't change with time. To understand a laser beam, we need to know how electric and magnetic fields change with time. Other important examples of time-dependent electromagnetic phenomena include high-speed circuits, transmission lines, radar, and optical communications.

Our study will culminate in Maxwell's equations for the electromagnetic field. These equations play a role in electricity and magnetism analogous to Newton's laws in mechanics. Maxwell's realization that light is an electromagnetic wave was perhaps the most important discovery of the 19th century.

35.1 *E* or *B?* It Depends on Your Perspective

It seems clear, after the last nine chapters, that charges create an electric field $\vec{E}$ and that moving charges, or currents, create a magnetic field $\vec{B}$. Charges other than the source charges always respond to $\vec{E}$, but only moving charges respond to $\vec{B}$. Consider the following, however.

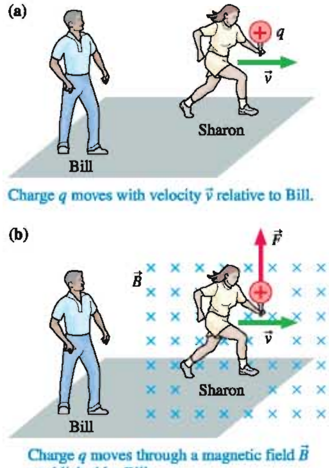
FIGURE 35.1a shows Sharon running past Bill with velocity $\vec{v}$ while carrying charge q. Bill sees a moving charge, and he knows that this charge creates a magnetic field. But from Sharon's perspective, the charge is at rest. Stationary charges don't create magnetic fields, so Sharon claims that the magnetic field is zero. Is there or is there not a magnetic field?

Or what about the situation in FIGURE 35.1b? This time Sharon runs through an external magnetic field $\vec{B}$ that Bill has created. Bill sees a charge moving through a magnetic field, so he knows there's a force $\vec{F} = q\vec{v} \times \vec{B}$ on the charge. Using the right-hand rule, Bill determines that the force points straight up. But for Sharon the charge is still at rest. Stationary charges don't experience magnetic forces, so Sharon claims that $\vec{F} = \vec{0}$.

Now, we may be a bit uncertain about magnetic fields because they are an abstract concept, but surely there can be no disagreement over forces. After all, either the charge is going to accelerate upward or it isn't, and Bill and Sharon should be able to agree on the outcome.

Here we have a genuine paradox, not merely faulty reasoning. This paradox has arisen because we have fields and forces that depend on velocity. The difficulty is that we haven't looked at the issue of velocity *with respect to what* or velocity *as measured by whom.* A closer look at how electromagnetic fields are viewed by two experimenters moving relative to each other will lead us to conclude that $\vec{E}$ and $\vec{B}$ are not, as we've been assuming, separate and independent entities. They are closely intertwined.

FIGURE 35.1 Sharon carries a charge past Bill.



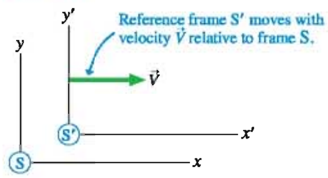
Charge q moves with velocity $\vec{v}$ relative to Bill.

Charge q moves through a magnetic field $\vec{B}$ established by Bill.

Galilean Relativity

We introduced reference frames and relative motion in Chapter 4, and a review of Section 4.4 is highly recommended. FIGURE 35.2 shows two reference frames that we'll call frame S and frame S′. Frame S′ moves with velocity $\vec{V}$ with respect to frame S. That is, an experimenter at rest in S sees the origin of S′ go past with velocity $\vec{V}$. Of course, an experimenter at rest in S′ would say that frame S has velocity $-\vec{V}$. We'll use an uppercase V for the velocity of reference frames, reserving lowercase v for the velocity of objects moving in the reference frames. There's no implication that either frame is "at rest." All we know is that the two frames move relative to each other.

FIGURE 35.2 Reference frames S and S′.

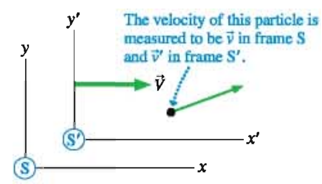


NOTE ▶ We will consider only reference frames that move with respect to each other at *constant* velocity—unchanging speed in a straight line. You learned in Chapter 4 that these are called *inertial reference frames,* and they are the reference frames in which Newton's laws are valid. ◀

FIGURE 35.3 shows a physical object, such as a charged particle. Experimenters in frame S measure the motion of the particle and find that its velocity *relative to frame S* is $\vec{v}$. At the same time, experimenters in S′ find that the particle's velocity *relative to frame S′* is $\vec{v}\,'$. In Chapter 4, we found that $\vec{v}$ and $\vec{v}\,'$ are related by

$$\vec{v}\,' = \vec{v} - \vec{V} \quad \text{or} \quad \vec{v} = \vec{v}\,' + \vec{V} \tag{35.1}$$

FIGURE 35.3 The particle's velocity is measured in both frame S and frame S′.



Equation 35.1, the *Galilean transformation of velocity,* allows us to transform a velocity measured in one reference frame into the velocity that would be measured by an experimenter in a different reference frame.

Suppose the particle in Figure 35.3 is accelerating. How does its acceleration $\vec{a}$, as measured by experimenters in frame S, compare to the acceleration $\vec{a}\,'$ measured in frame S′? We can answer this question by taking the time derivative of Equation 35.1:

$$\frac{d\vec{v}\,'}{dt} = \frac{d\vec{v}}{dt} - \frac{d\vec{V}}{dt}$$

The derivatives of $\vec{v}$ and $\vec{v}\,'$ are the particle's accelerations $\vec{a}$ and $\vec{a}\,'$ in frames S and S′. But $\vec{V}$ is a *constant* velocity, so $d\vec{V}/dt = 0$. Thus the Galilean transformation of acceleration is simply

$$\vec{a}\,' = \vec{a} \tag{35.2}$$

Sharon and Bill may measure different positions and velocities for a particle, but they *agree* on its acceleration. This agreement is important because acceleration is directly related to force. An experimenter in frame S would find that a force $\vec{F} = m\vec{a}$ is acting on the particle. Similarly, the force measured in frame S′ is $\vec{F}' = m\vec{a}'$. But $\vec{a}' = \vec{a}$, hence

$$\vec{F}' = \vec{F} \tag{35.3}$$

Experimenters in all inertial reference frames agree about the force acting on a particle. This conclusion is the key to understanding how different experimenters see electric and magnetic fields.

The Transformation of Electric and Magnetic Fields

Now we're ready to return to the paradox that opened this section. Imagine that Bill has measured the electric field $\vec{E}$ and the magnetic field $\vec{B}$ in frame S. Our investigations thus far give us no reason to think that Sharon's measurements of the fields will differ from Bill's. After all, it seems like the fields are just "there," waiting to be measured. Thus our expectation is that Sharon, in frame S′, will measure $\vec{E}' = \vec{E}$ and $\vec{B}' = \vec{B}$.

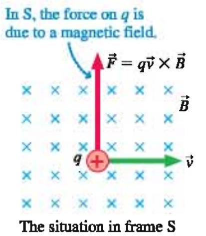


FIGURE 35.4 A charge moves through a magnetic field in frame S and experiences a magnetic force.

To find out if this is true, Bill establishes a region of space in which there is a uniform magnetic field $\vec{B}$ but $\vec{E} = \vec{0}$. Then, as shown in **FIGURE 35.4**, he shoots a positive charge q through the magnetic field. At an instant when q is moving horizontally with velocity $\vec{v}$, the net force $\vec{F} = q(\vec{E} + \vec{v} \times \vec{B}) = q\vec{v} \times \vec{B}$ is straight up.

NOTE ▶ The combined electric and magnetic force on a charged particle, $\vec{F} = q(\vec{E} + \vec{v} \times \vec{B})$, is often called the *Lorentz Force*. ◀

Suppose that Sharon, in frame S′, moves alongside the charge with velocity $\vec{V} = \vec{v}$. In other words, the charge is at rest in S′. We've just seen that experimenters in S and S′ agree about forces, so if Bill finds an upward force in S, then Sharon *must* observe an upward force in S′. But there is *no* magnetic force on a stationary charge, so how can this be?

Because Sharon in S′ sees a stationary charge with an upward force depending on the size of q, her only possible conclusion is that there is an upward-pointing *electric field*. After all, the electric field was initially defined in terms of the force experienced by a stationary charge. If the electric field in frame S′ is $\vec{E}'$, then the force on the charge is $\vec{F}' = q\vec{E}'$. But we know that $\vec{F}' = \vec{F}$, and Bill has already measured $\vec{F} = q\vec{v} \times \vec{B} = q\vec{V} \times \vec{B}$. Thus we're led to the conclusion that

$$\vec{E}' = \vec{V} \times \vec{B} \tag{35.4}$$

As Sharon runs past Bill, she finds that at least part of Bill's magnetic field has become an electric field! **Whether a field is seen as "electric" or "magnetic" depends on the motion of the reference frame relative to the sources of the field.**

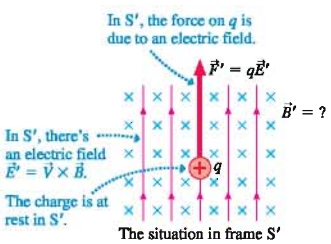

FIGURE 35.5 In frame S′ the charge experiences an electric force.

FIGURE 35.5 shows the situation from Sharon's perspective. The force on charge q is the same as the force measured by Bill in Figure 35.4, but Sharon attributes this force to an electric field rather than a magnetic field. (Sharon needs a moving charge to measure magnetic forces, so we can't determine from this experiment whether or not Sharon experiences a magnetic field $\vec{B}'$. We'll return to this issue.)

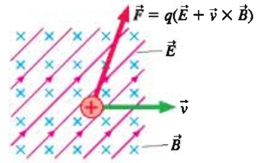
More generally, suppose that an experimenter in S creates both an electric field $\vec{E}$ and a magnetic field $\vec{B}$. A charge moving with velocity $\vec{v}$ experiences the Lorentz force $\vec{F} = q(\vec{E} + \vec{v} \times \vec{B})$ shown in **FIGURE 35.6a**. The charge is at rest in frame S′ that moves with velocity $\vec{V} = \vec{v}$, so the force in S′ can be due only to an electric field, $\vec{F}' = q\vec{E}'$. Equating $\vec{F}$ and $\vec{F}'$, because experimenters in all inertial reference frames agree about forces, we find that

$$\vec{E}' = \vec{E} + \vec{V} \times \vec{B} \tag{35.5}$$

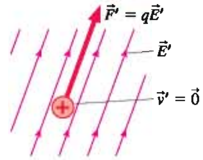
Equation 35.5 transforms the electric and magnetic fields in S into the electric field measured in frame S′. **FIGURE 35.6b** shows the outcome.

FIGURE 35.6 A charge in frame S experiences electric and magnetic forces. The charge experiences the same force in frame S′, but it is due only to an electric field.

(a) The electric and magnetic fields in frame S



(b) The electric field in frame S′, where the charged particle is at rest



EXAMPLE 35.1 Transforming the electric field

A proton moves in the combined fields $\vec{E} = 10{,}000\hat{\imath}$ V/m and $\vec{B} = 0.10\hat{\imath}$ T. These are the fields in the laboratory. What is the electric field in a reference frame moving through the laboratory with velocity $\vec{V} = 1.0 \times 10^5\hat{\jmath}$ m/s?

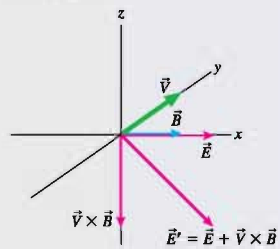
VISUALIZE FIGURE 35.7 shows the geometry. $\vec{E}$ and $\vec{B}$ are parallel to each other, along the x-axis, while velocity $\vec{V}$ of frame S′ is in the y-direction. Thus $\vec{V} \times \vec{B}$ points in the negative z-direction.

SOLVE $\vec{V}$ and $\vec{B}$ are perpendicular, so the magnitude of $\vec{V} \times \vec{B}$ is $VB = (1.0 \times 10^5 \text{ m/s}) \times (0.10 \text{ T}) = 10{,}000$ V/m. Thus the electric field in frame S′ is

$$\vec{E}' = \vec{E} + \vec{V} \times \vec{B} = (10{,}000\hat{\imath} - 10{,}000\hat{k}) \text{ V/m}$$
$$= (14{,}000 \text{ V/m, } 45^\circ \text{ below the } x\text{-axis})$$

ASSESS A stationary charge in frame S′ experiences an electric force directed 45° below the x-axis. The force in frame S is the same, but, because the charge is moving in S, the force is attributed to a combination of electric and magnetic forces.

FIGURE 35.7 Finding the direction of field $\vec{E}'$.



Equation 35.5 transforms the fields $\vec{E}$ and $\vec{B}$ of frame S into the electric field $\vec{E}'$ of frame S′. In order to find a transformation equation for $\vec{B}'$, FIGURE 35.8a shows charge q at rest in frame S. Bill measures the fields of a stationary point charge, which we know are

$$\vec{E} = \frac{1}{4\pi\epsilon_0}\frac{q}{r^2}\hat{r} \qquad \vec{B} = \vec{0}$$

What are the fields at this point in space as measured by Sharon in frame S′? We can use Equation 35.5 to find $\vec{E}'$. Because $\vec{B} = \vec{0}$, the electric field in frame S′ is

$$\vec{E}' = \vec{E} = \frac{1}{4\pi\epsilon_0}\frac{q}{r^2}\hat{r} \tag{35.6}$$

In other words, Coulomb's law is still valid in a frame in which the point charge is moving. We needed to confirm that this is so, rather than just assuming it, because Coulomb's law was introduced in a frame in which the charges were at rest.

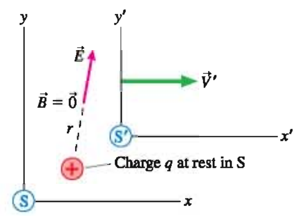
But Sharon also measures a magnetic field $\vec{B}'$ because, as seen in FIGURE 35.8b, charge q is moving away from her with velocity $\vec{v}' = -\vec{V}$. The magnetic field of a moving point charge is given by the Biot-Savart law, thus

$$\vec{B}' = \frac{\mu_0}{4\pi}\frac{q}{r^2}\vec{v}' \times \hat{r} = -\frac{\mu_0}{4\pi}\frac{q}{r^2}\vec{V} \times \hat{r} \tag{35.7}$$

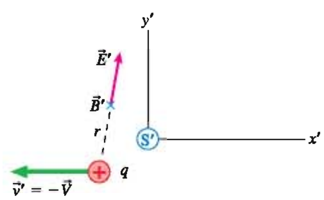
where we used the fact that the charge's velocity in frame S′ is $\vec{v}' = -\vec{V}$.

FIGURE 35.8 A charge at rest in frame S is moving in frame S′ and creates a magnetic field $\vec{B}'$.

(a) In frame S, the static charge creates an electric field but no magnetic field.



(b) In frame S′, the moving charge creates both an electric and a magnetic field.



It will be useful to rewrite Equation 35.7 as

$$\vec{B}' = -\frac{\mu_0}{4\pi}\frac{q}{r^2}\vec{V} \times \hat{r} = -\epsilon_0\mu_0\vec{V} \times \left(\frac{1}{4\pi\epsilon_0}\frac{q}{r^2}\hat{r}\right)$$

The expression in parentheses is simply $\vec{E}$, the electric field in frame S, so we find

$$\vec{B}' = -\epsilon_0\mu_0\vec{V} \times \vec{E} \tag{35.8}$$

Equation 35.8 expresses the remarkable idea that **the Biot-Savart law for the magnetic field of a moving point charge is nothing other than the Coulomb electric field of a stationary point charge transformed into a moving reference frame.**

We will assert without proof that if the experimenters in frame S create a magnetic field $\vec{B}$ in addition to the electric field $\vec{E}$, then the field $\vec{B}'$ measured in frame S′ is

$$\vec{B}' = \vec{B} - \epsilon_0\mu_0\vec{V} \times \vec{E} \tag{35.9}$$

This is a general transformation matching Equation 35.5 for the electric field $\vec{E}'$.

Notice something interesting. The constant μ_0 has units of T m/A; those of ϵ_0 are C^2/Nm^2. By definition, 1 T = 1 N/A m and 1 A = 1 C/s. Consequently, the units of $\epsilon_0\mu_0$ turn out to be s^2/m^2. In other words, the quantity $1/\sqrt{\epsilon_0\mu_0}$, with units of m/s, is a velocity. But what velocity? The constants are well known from measurements of static electric and magnetic fields, so we can compute

$$\frac{1}{\sqrt{\epsilon_0\mu_0}} = \frac{1}{\sqrt{(1.26 \times 10^{-6}\ \mathrm{Tm/A})(8.85 \times 10^{-12}\ \mathrm{C^2/Nm^2})}} = 3.00 \times 10^8\ \mathrm{m/s}$$

Can this be a coincidence? Of all the possible values you might get from evaluating $1/\sqrt{\epsilon_0\mu_0}$, what are the chances it would come out to equal c, the speed of light? Maxwell was the first to discover this unexpected connection between the speed of light and the constants that govern the sizes of electric and magnetic forces, and he knew at once that this couldn't be a random coincidence. In Section 35.5 we'll show that electric and magnetic fields can exist as a *traveling wave,* and that the wave speed is predicted by the theory to be none other than

$$v_{em} = c = \frac{1}{\sqrt{\epsilon_0\mu_0}} \tag{35.10}$$

For now, we'll go ahead and write $\epsilon_0\mu_0 = 1/c^2$. With this, our **Galilean field transformation equations** are

$$\begin{aligned} \vec{E}' &= \vec{E} + \vec{V} \times \vec{B} & & & \vec{E} &= \vec{E}' - \vec{V} \times \vec{B}' \\ & & \text{or} & & & \\ \vec{B}' &= \vec{B} - \frac{1}{c^2}\vec{V} \times \vec{E} & & & \vec{B} &= \vec{B}' + \frac{1}{c^2}\vec{V} \times \vec{E}' \end{aligned} \tag{35.11}$$

where $\vec{V}$ is the velocity of frame S′ relative to frame S and where, to reiterate, the fields are measured *at the same point in space* by experimenters *at rest* in each reference frame.

NOTE ► We'll see shortly that these equations are valid only if $V \ll c$. ◄

We can no longer believe that electric and magnetic fields have a separate, independent existence. Changing from one reference frame to another mixes and rearranges the fields. Different experimenters watching an event will agree on the outcome, such as the deflection of a charged particle, but they will ascribe it to different combinations of fields. Our conclusion is that **there is just a single electromagnetic field that presents different faces, in terms of $\vec{E}$ and $\vec{B}$, to different viewers.** The whole concept of fields is beginning to look more complex, but also more interesting, than we first would have guessed!

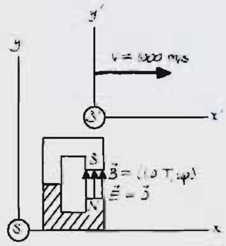
EXAMPLE 35.2 Two views of a magnetic field

The 1.0 T magnetic field of a laboratory magnet points upward. A rocket flies past the laboratory, parallel to the ground, at 1000 m/s. What are the fields between the magnet's pole tips as measured by a scientist on board the rocket?

MODEL Assume that the laboratory and rocket reference frames are inertial reference frames.

VISUALIZE FIGURE 35.9 shows the magnet and establishes the reference frames.

FIGURE 35.9 A rocket flies past a laboratory magnet.



SOLVE The fields in the laboratory frame are $\vec{B} = 1.0\hat{j}$ T and $\vec{E} = \vec{0}$. Frame S′, the frame of the rocket, moves with velocity $\vec{V} = 1000\hat{i}$ m/s. Equations 35.11 transform the fields measured in the laboratory to the rocket frame S′. We find

$$\vec{E}' = \vec{E} + \vec{V} \times \vec{B} = \vec{V} \times \vec{B}$$

$$\vec{B}' = \vec{B} - \frac{1}{c^2}\vec{V} \times \vec{E} = \vec{B} = 1.0\hat{j}\text{ T}$$

From the right-hand rule, $\vec{V} \times \vec{B}$ is out of the page, or in the $\hat{k}$-direction. $\vec{V}$ and $\vec{B}$ are perpendicular, so

$$\vec{E}' = VB\hat{k} = 1000\hat{k}\text{ V/m} = (1000\text{ V/m, out of page})$$

Thus the rocket scientist measures

$$\vec{B}' = 1.0\hat{j}\text{ T} \quad \text{and} \quad \vec{E}' = 1000\hat{k}\text{ V/m}$$

ASSESS The transformation equations apply only to fields measured at the *same* point in space. Thus these results apply to measurements made between the magnet's pole tips, where $\vec{B}$ is known, but not to other points in the laboratory.

Almost Relativity

FIGURE 35.10 shows two positive charges moving side by side through frame S with velocity $\vec{v}$. Charge q_1 creates an electric field and a magnetic field at the position of charge q_2. These are

$$\vec{E}_1 = \frac{1}{4\pi\epsilon_0}\frac{q_1}{r^2}\hat{j} \quad \text{and} \quad \vec{B}_1 = \frac{\mu_0}{4\pi}\frac{q_1 v}{r^2}\hat{k}$$

where r is the distance between the charges and we've used $\hat{r} = \hat{j}$ and $\vec{v} \times \hat{r} = v\hat{k}$.

How are the fields seen in frame S′, which moves with $\vec{V} = \vec{v}$ and in which the charges are at rest? From the field transformation equations,

$$\begin{aligned}\vec{B}_1' &= \vec{B}_1 - \frac{1}{c^2}\vec{V} \times \vec{E}_1 = \frac{\mu_0}{4\pi}\frac{q_1 v}{r^2}\hat{k} - \frac{1}{c^2}\left(v\hat{i} \times \frac{1}{4\pi\epsilon_0}\frac{q_1}{r^2}\hat{j}\right)\\ &= \frac{\mu_0}{4\pi}\frac{q_1 v}{r^2}\left(1 - \frac{1}{\epsilon_0\mu_0 c^2}\right)\hat{k}\end{aligned} \tag{35.12}$$

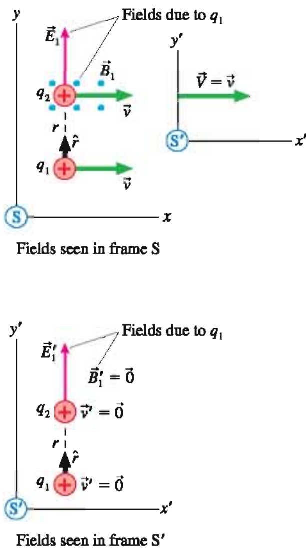
where we used $\hat{i} \times \hat{j} = \hat{k}$. But $\epsilon_0\mu_0 = 1/c^2$, so the term in parentheses is zero and $\vec{B}' = \vec{0}$. This result was expected because q_1 is at rest in S′ and shouldn't create a magnetic field.

The transformation of the electric field is

$$\begin{aligned}\vec{E}_1' &= \vec{E}_1 + \vec{V} \times \vec{B}_1 = \frac{1}{4\pi\epsilon_0}\frac{q_1}{r^2}\hat{j} + v\hat{i} \times \frac{\mu_0}{4\pi}\frac{q_1 v}{r^2}\hat{k}\\ &= \frac{1}{4\pi\epsilon_0}\frac{q_1}{r^2}(1 - \epsilon_0\mu_0 v^2)\hat{j} = \frac{1}{4\pi\epsilon_0}\frac{q_1}{r^2}\left(1 - \frac{v^2}{c^2}\right)\hat{j}\end{aligned} \tag{35.13}$$

where we used $\hat{i} \times \hat{k} = -\hat{j}$ and $\epsilon_0\mu_0 = 1/c^2$.

FIGURE 35.10 Two charges moving parallel to each other.



But now we have a problem. In frame S′, where the two charges are at rest and separated by distance r, the electric field due to charge q_1 should be simply

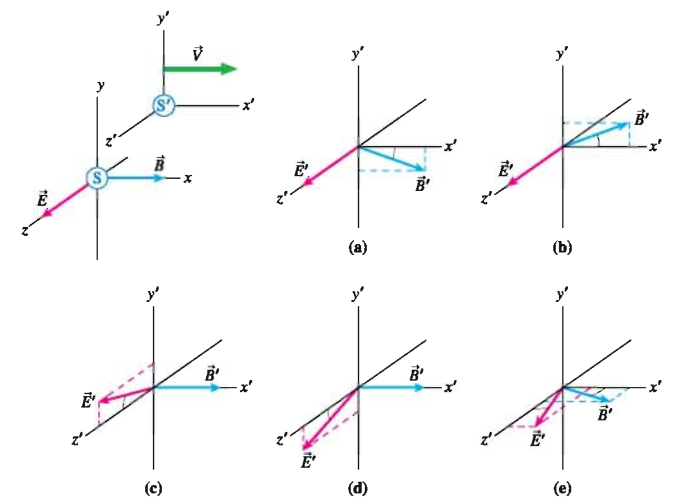
$$\vec{E}_1{}' = \frac{1}{4\pi\epsilon_0}\frac{q_1}{r^2}\hat{j}$$

The transformation equations have given a "wrong" result for the electric field $\vec{E}'$.

It turns out that the field transformations of Equations 35.11, which are based on Galilean relativity, aren't quite right. We would need Einstein's relativity—a topic that we'll take up in Chapter 37—to give the correct transformations. However, the *Galilean* transformations in Equations 35.11 are equivalent to the relativistically correct transformations when $v \ll c$, in which case $v^2/c^2 \ll 1$. You can see that the two expressions for $\vec{E}_1{}'$ do, in fact, agree if v^2/c^2 can be neglected.

Thus our use of the field transformation equations has an additional rule: Set v^2/c^2 to zero. This is an acceptable rule for speeds $v < 10^7$ m/s. Even with this limitation, our investigation has provided us with a deeper understanding of electric and magnetic fields.

STOP TO THINK 35.1 Which diagram shows the fields in frame S′?



Faraday's Law Revisited

The transformation of electric and magnetic fields can give us new insight into Faraday's law. **FIGURE 35.11a** shows a reference frame S, which we can call the laboratory frame, in which a conducting loop is moving with velocity $\vec{v}$ into a magnetic field. You learned in Chapter 34 that the magnetic field exerts an upward force $\vec{F}_B = q\vec{v} \times \vec{B} = (qvB$, upward) on the charges in the leading edge of the wire, creating an emf $\mathcal{E} = vLB$ and an induced current in the loop. We called this a *motional emf.*

How do things appear to an experimenter who is in frame S′ that moves with the loop at velocity $\vec{V} = \vec{v}$ and for whom the loop is at rest? We have learned the impor-

tant lesson that experimenters in different inertial reference frames agree about the outcome of any experiment; hence an experimenter in S′ agrees that there is an induced current in the loop. But the charges are at rest in frame S′, so there cannot be any magnetic force on them. How is the emf established in frame S′?

We can use the field transformations to determine that the fields in S′ are

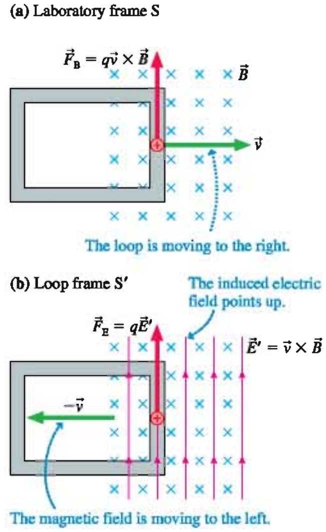
$$\vec{E}' = \vec{E} + \vec{v} \times \vec{B} = \vec{v} \times \vec{B}$$
$$\vec{B}' = \vec{B} - \frac{1}{c^2}\vec{v} \times \vec{E} = \vec{B} \qquad (35.14)$$

where we used the fact that $\vec{E} = \vec{0}$ in the laboratory frame.

An experimenter in the loop's frame sees not only a magnetic field but also the electric field $\vec{E}'$ shown in FIGURE 35.11b. The magnetic field exerts no force on the charges, because they're at rest in this frame, but the electric field does. The force on charge q is $\vec{F}_E = q\vec{E}' = q\vec{v} \times \vec{B} = (qvB, \text{upward})$. This is the same force as was measured in the laboratory frame, so it will cause the same emf and the same current. The outcome is identical, as we knew it had to be, but the experimenter in S′ attributes the emf to an electric field whereas the experimenter in S attributes it to a magnetic field.

Field $\vec{E}'$ is, in fact, the *induced electric field* of Faraday's law. Faraday's law, fundamentally, is a statement that **a changing magnetic field creates an electric field.** But only in frame S′, the frame of the loop, is the magnetic field changing. Thus the induced electric field is seen in the loop's frame but not in the laboratory frame. The induced electric field is a *non-Coulomb* field because it is not created by static charges. It is a field that has been created in a new way.

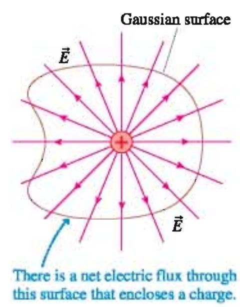
FIGURE 35.11 A motional emf as seen in two different reference frames.



35.2 The Field Laws Thus Far

Let's remind ourselves where we are in terms of discovering laws about the electromagnetic field. Gauss's law, which you studied in Chapter 28, states a very general property of the electric field. It says that charges create electric fields in such a way that the electric flux of the field is the same through *any* closed surface surrounding the charges. FIGURE 35.12 illustrates this idea by showing the field lines passing through a Gaussian surface enclosing a charge.

FIGURE 35.12 A Gaussian surface enclosing a charge.



The mathematical statement of Gauss's law for the electric field says that for any *closed* surface enclosing total charge Q_{in}, the net electric flux through the surface is

$$(\Phi_e)_{\text{closed surface}} = \oint \vec{E} \cdot d\vec{A} = \frac{Q_{in}}{\epsilon_0} \qquad (35.15)$$

The circle on the integral sign indicates that the integration is over a closed surface. Gauss's law is the first of what will turn out to be four *field equations*.

There's an analogous equation for magnetic fields, an equation we implied in Chapter 33—where we noted there are no magnetic monopoles—but didn't explicitly write down. FIGURE 35.13 on the next page shows a Gaussian surface around a magnetic dipole. Magnetic field lines form continuous curves, without starting or stopping, so every field line leaving the surface at some point must reenter it at another. Consequently, the net magnetic flux over a *closed* surface is zero.

We've shown only one surface and one magnetic field, but this conclusion turns out to be a general property of magnetic fields. Because every north pole is accompanied by a south pole, we can't enclose a "net pole" within a surface. Thus Gauss's law for magnetic fields is

$$(\Phi_m)_{\text{closed surface}} = \oint \vec{B} \cdot d\vec{A} = 0 \qquad (35.16)$$

FIGURE 35.13 There is no net flux through a Gaussian surface around a magnetic dipole.

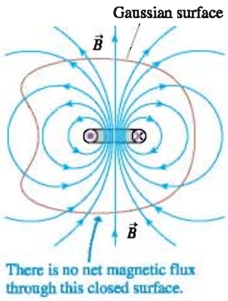


FIGURE 35.14 Ampère's law relates the line integral of $\vec{B}$ around curve C to the current passing through surface S.

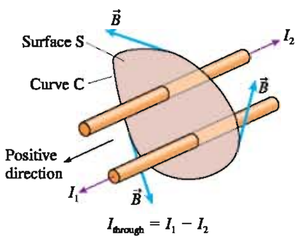


Equation 35.15 is the mathematical statement that Coulomb electric field lines start and stop on charges. Equation 35.16 is the mathematical statement that magnetic field lines form closed loops; they don't start or stop (i.e., there are no magnetic monopoles). These two versions of Gauss's law are important statements about what types of fields can and cannot exist. They will become two of Maxwell's equations.

The third field law we've established is Faraday's law:

$$\mathcal{E} = \oint \vec{E} \cdot d\vec{s} = -\frac{d\Phi_m}{dt} \tag{35.17}$$

where the line integral of $\vec{E}$ is around the closed curve that bounds the surface through which the magnetic flux Φ_m is calculated. Equation 35.17 is the mathematical statement that an electric field (and thus an emf $\mathcal{E}$) can also be created by a changing magnetic field. The correct use of Faraday's law requires a convention for determining when fluxes are positive and negative. The sign convention will be given in the next section, where we discuss the fourth and last field equation—an analogous equation for magnetic fields.

35.3 The Displacement Current

We introduced Ampère's law in Chapter 33 as an alternative to the Biot-Savart law for calculating the magnetic field of a current. Whenever total current $I_{through}$ passes through an area bounded by a closed curve, the line integral of the magnetic field around the curve is

$$\oint \vec{B} \cdot d\vec{s} = \mu_0 I_{through} \tag{35.18}$$

FIGURE 35.14 illustrates the geometry of Ampère's law. The sign of each current can be determined by using Tactics Box 35.1. In this case, $I_{through} = I_1 - I_2$.

TACTICS BOX 35.1 Determining the signs of flux and current (MP)

1. For a surface S bounded by a closed curve C, choose either the clockwise (cw) or counterclockwise (ccw) direction around C.
2. Curl the fingers of your *right* hand around the curve in the chosen direction, with your thumb perpendicular to the surface. Your thumb defines the positive direction.
   - A flux Φ through the surface is positive if the field is in the same direction as your thumb, negative if the field is in the opposite direction.
   - A current through the surface in the direction of your thumb is positive, in the direction opposite your thumb is negative.

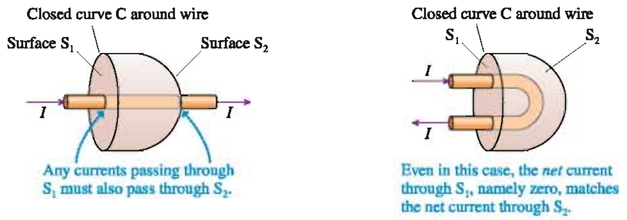
Exercises 4–6

Ampère's law is the formal statement that **currents create magnetic fields.** Although Ampère's law can be used to calculate magnetic fields in situations with a high degree of symmetry, it is more important as a statement about what types of magnetic field can and cannot exist.

Something Is Missing

Nothing restricts the bounded surface of Ampère's law to being flat. It's not hard to see that any current passing through surface S_1 in **FIGURE 35.15** must also pass through the curved surface S_2. To interpret Ampère's law properly, we have to say that the current $I_{through}$ is the net current passing through *any* surface S that is bounded by curve C.

FIGURE 35.15 The *net* current passing through the flat surface S_1 also passes through the curved surface S_2.



But this leads to an interesting puzzle. FIGURE 35.16a shows a capacitor being charged. Current I, from the left, brings positive charge to the left capacitor plate. The same current carries charges away from the right capacitor plate, leaving the right plate negatively charged. This is a perfectly ordinary current in a conducting wire, and you can use the right-hand rule to verify that its magnetic field is as shown.

Curve C is a closed curve encircling the wire on the left. The current passes through surface S_1, a flat surface across C, and we could use Ampère's law to find that the magnetic field is that of a straight wire. But what happens if we try to use surface S_2 to determine I_{through}? Ampère's law says that we can consider *any* surface bounded by curve C, and surface S_2 certainly qualifies. But *no* current passes through S_2. Charges are brought to the left plate of the capacitor and charges are removed from the right plate, but *no* charge moves across the gap between the plates. Surface S_1 has $I_{\text{through}} = I$, but surface S_2 has $I_{\text{through}} = 0$. Another dilemma!

It would appear that Ampère's law is either wrong or incomplete. Maxwell was the first to recognize the seriousness of this problem. He noted that there may be no current passing through S_2, but, as FIGURE 35.16b shows, there is an electric flux Φ_e through S_2 due to the electric field inside the capacitor. Furthermore, this flux is *changing* with time as the capacitor charges and the electric field strength grows. Faraday had discovered the significance of a changing magnetic flux, but no one had considered a changing electric flux.

The current I passes through S_1, so Ampère's law applied to S_1 gives

$$\oint \vec{B} \cdot d\vec{s} = \mu_0 I_{\text{through}} = \mu_0 I$$

We believe this result because it gives the correct magnetic field for a current-carrying wire. Now the line integral depends only on the magnetic field at points on curve C, so its value won't change if we choose a different surface S to evaluate the current. The problem is with the right side of Ampère's law, which would incorrectly give zero if applied to surface S_2. We need to modify the right side of Ampère's law to recognize that an electric flux rather than a current passes through S_2.

The electric flux between two capacitor plates of surface area A is

$$\Phi_e = EA$$

The capacitor's electric field is $E = Q/\epsilon_0 A$; hence the flux is actually independent of the plate size:

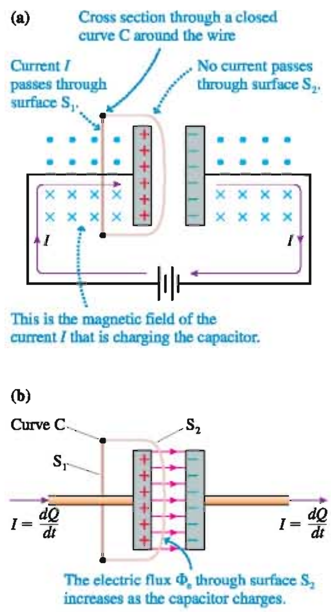
$$\Phi_e = \frac{Q}{\epsilon_0 A} A = \frac{Q}{\epsilon_0} \tag{35.19}$$

The *rate* at which the electric flux is changing is

$$\frac{d\Phi_e}{dt} = \frac{1}{\epsilon_0}\frac{dQ}{dt} = \frac{I}{\epsilon_0} \tag{35.20}$$

where we used $I = dQ/dt$. The flux is changing with time at a rate directly proportional to the charging current I.

FIGURE 35.16 There is no current through surface S_2 as the capacitor charges, but there is a changing electric flux.



Equation 35.20 suggests that the quantity $\epsilon_0(d\Phi_e/dt)$ is in some sense "equivalent" to current I. Maxwell called the quantity

$$I_{disp} = \epsilon_0 \frac{d\Phi_e}{dt} \tag{35.21}$$

the **displacement current.** He had started with a fluid-like model of electric and magnetic fields, and the displacement current was analogous to the displacement of a fluid. The fluid model has since been abandoned, but the name lives on despite the fact that nothing is actually being displaced.

Maxwell hypothesized that the displacement current was the "missing" piece of Ampère's law, so he modified Ampère's law to read

$$\oint \vec{B} \cdot d\vec{s} = \mu_0(I_{through} + I_{disp}) = \mu_0\left(I_{through} + \epsilon_0 \frac{d\Phi_e}{dt}\right) \tag{35.22}$$

Equation 35.22 is now known as the Ampère-Maxwell law. When applied to Figure 35.16b, the Ampère-Maxwell law gives

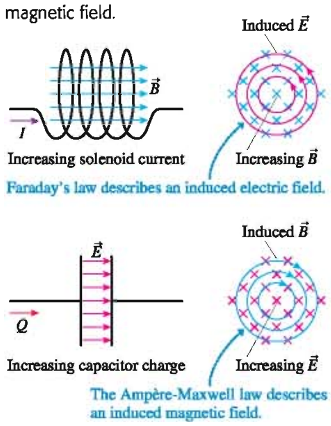
$$S_1: \quad \oint \vec{B} \cdot d\vec{s} = \mu_0\left(I_{through} + \epsilon_0 \frac{d\Phi_e}{dt}\right) = \mu_0(I + 0) = \mu_0 I$$

$$S_2: \quad \oint \vec{B} \cdot d\vec{s} = \mu_0\left(I_{through} + \epsilon_0 \frac{d\Phi_e}{dt}\right) = \mu_0(0 + I) = \mu_0 I$$

where, for surface S_2, we used Equation 35.20 for $d\Phi_e/dt$. Surfaces S_1 and S_2 now both give the same result for the line integral of $\vec{B} \cdot d\vec{s}$ around the closed curve C.

NOTE ► The displacement current I_{disp} between the capacitor plates is numerically equal to the current I in the wires to and from the capacitor, so in some sense it allows "current" to be conserved all the way through the capacitor. Nonetheless, the displacement current is *not* a flow of charge. The displacement current is equivalent to a real current in that it creates the same magnetic field, but it does so with a changing electric flux rather than a flow of charge. ◄

FIGURE 35.17 The close analogy between an induced electric field and an induced magnetic field.



The Induced Magnetic Field

Ordinary Coulomb electric fields are created by charges, but a second way to create an electric field is by having a changing magnetic field. That's Faraday's law. Ordinary magnetic fields are created by currents, but now we see that a second way to create a magnetic field is by having a changing electric field. Just as the electric field created by a changing $\vec{B}$ is called an induced electric field, the magnetic field created by a changing $\vec{E}$ is called an *induced magnetic field.*

FIGURE 35.17 shows the close analogy between induced electric fields, governed by Faraday's law, and induced magnetic fields, governed by the second term in the Ampère-Maxwell law. An increasing solenoid current causes an increasing magnetic field. The changing magnetic field, in turn, induces a circular electric field. The negative sign in Faraday's law dictates that the induced electric field direction is ccw when seen looking along the magnetic field direction.

An increasing capacitor charge causes an increasing electric field. The changing electric field, in turn, induces a circular magnetic field. But the sign of the Ampère-Maxwell law is positive, the opposite of the sign of Faraday's law, so the induced magnetic field direction is cw when you're looking along the electric field direction.

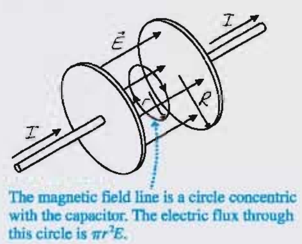
EXAMPLE 35.3 The fields inside a charging capacitor

A 2.0-cm-diameter parallel-plate capacitor with a 1.0 mm spacing is being charged at the rate 0.50 C/s. What is the magnetic field strength inside the capacitor at a point 0.50 cm from the axis?

MODEL The electric field inside a parallel-plate capacitor is uniform. As the capacitor is charged, the changing electric field induces a magnetic field.

VISUALIZE FIGURE 35.18 shows the fields. The induced magnetic field lines are circles concentric with the capacitor.

FIGURE 35.18 The magnetic field strength is found by integrating around a closed curve of radius r.



SOLVE The electric field of a parallel-plate capacitor is $E = Q/\epsilon_0 A = Q/\epsilon_0 \pi R^2$. The electric flux through the circle of radius r (not the full flux of the capacitor) is

$$\Phi_e = \pi r^2 E = \pi r^2 \frac{Q}{\epsilon_0 \pi R^2} = \frac{r^2}{R^2}\frac{Q}{\epsilon_0}$$

Thus the Ampère-Maxwell law is

$$\oint \vec{B} \cdot d\vec{s} = \epsilon_0 \mu_0 \frac{d\Phi_e}{dt} = \epsilon_0 \mu_0 \frac{d}{dt}\left(\frac{r^2}{R^2}\frac{Q}{\epsilon_0}\right) = \mu_0 \frac{r^2}{R^2}\frac{dQ}{dt}$$

The magnetic field is everywhere tangent to the circle of radius r, so the integral of $\vec{B} \cdot d\vec{s}$ around the circle is simply $BL = 2\pi r B$. With this value for the line integral, the Ampère-Maxwell law becomes

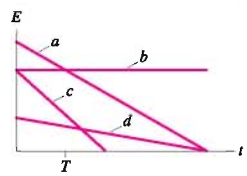
$$2\pi r B = \mu_0 \frac{r^2}{R^2}\frac{dQ}{dt}$$

and thus

$$B = \frac{\mu_0}{2\pi}\frac{r}{R^2}\frac{dQ}{dt} = (2.0 \times 10^{-7}\ \text{Tm/A})\frac{0.0050\ \text{m}}{(0.010\ \text{m})^2}(0.50\ \text{C/s})$$
$$= 5.0 \times 10^{-6}\ \text{T}$$

If a changing magnetic field can induce an electric field and a changing electric field can induce a magnetic field, what happens when both fields change simultaneously? That is the question that Maxwell was finally able to answer after he modified Ampère's law to include the displacement current, and it is the subject to which we turn next.

STOP TO THINK 35.3 The electric field in four identical capacitors is shown as a function of time. Rank in order, from largest to smallest, the magnetic field strength at the outer edge of the capacitor at time T.



35.4 Maxwell's Equations

James Clerk Maxwell was a young, mathematically brilliant Scottish physicist. In 1855, barely 24 years old and having graduated from Cambridge University just two years earlier, he presented a paper to the Cambridge Philosophical Society entitled "On Faraday's Lines of Force." It had been 30 years and more since the major discoveries of Oersted, Ampère, Faraday, and others, but electromagnetism remained a loose collection of facts and "rules of thumb" without a consistent theory to link these ideas together.

Maxwell's goal, first enunciated in his paper of 1855, was to synthesize this body of knowledge and to place it in a proper mathematical framework. His desire was nothing less than to form a complete *theory* of electromagnetic fields. It took 10 years, until papers published in 1865 and 1868 laid out the theory in a form that looks familiar to us today. The critical step along the way was his recognition of the need to include a displacement-current term in Ampère's law.

Maxwell's theory of electromagnetism is embodied in four equations that we today call **Maxwell's equations.** These are

$\oint \vec{E} \cdot d\vec{A} = \dfrac{Q_{in}}{\epsilon_0}$	Gauss's law
$\oint \vec{B} \cdot d\vec{A} = 0$	Gauss's law for magnetism
$\oint \vec{E} \cdot d\vec{s} = -\dfrac{d\Phi_m}{dt}$	Faraday's law
$\oint \vec{B} \cdot d\vec{s} = \mu_0 I_{through} + \epsilon_0 \mu_0 \dfrac{d\Phi_e}{dt}$	Ampère-Maxwell law

You've seen all of these equations earlier in this chapter. It was Maxwell who first wrote them in a consistent mathematical form similar to this. (Not exactly the same, because our present-day vector notation wasn't developed until the 1890s, but Maxwell's versions were mathematically equivalent.) Neither Gauss nor Faraday nor Ampère would recognize these equations, but Maxwell had succeeded in capturing their physical ideas in a concise mathematical form.

Maxwell's claim is that these four equations are a *complete* description of electric and magnetic fields. They tell us how fields are created by charges and currents, and also how fields can be induced by the changing of other fields. We need one more equation for completeness, an equation that tells us how matter responds to electromagnetic fields. The general force equation

$$\vec{F} = q(\vec{E} + \vec{v} \times \vec{B}) \qquad \text{(Lorentz force law)}$$

is known as the *Lorentz force law.* **Maxwell's equations for the fields, together with the Lorentz force law to tell us how matter responds to the fields, form the complete theory of electromagnetism.**

Maxwell's equations bring us to the pinnacle of classical physics. Except at the quantum level of photons, these equations describe everything that is known about electromagnetic phenomena. In fact, they predict many new phenomena not known to Maxwell or his contemporaries, and they're the basis for all of modern circuit theory, electrical engineering, and other electromagnetic technology. When combined with Newton's three laws of motion, his law of gravity, and the first and second laws of thermodynamics, we have all of classical physics—a total of just 11 equations.

Classical physics

- Newton's first law
- Newton's second law
- Newton's third law
- Newton's law of gravity
- Gauss's law
- Gauss's law for magnetism
- Faraday's law
- Ampère-Maxwell law
- Lorentz force law
- First law of thermodynamics
- Second law of thermodynamics

While some physicists might quibble over whether all 11 are truly fundamental, the important point is not the exact number but how few equations we need to describe the overwhelming majority of our experience of the physical world. It seems as if we could have written them all on page 1 of this book and been finished, but it doesn't work that way. Each of these equations is the synthesis of a tremendous number of physical phenomena and conceptual developments. To know physics isn't just to know the equations, but to know what the equations *mean* and how they're used. That's why it's taken us so many chapters and so much effort to get to this point. Each equation is a shorthand way to summarize a book's worth of information!

Let's summarize the physical meaning of the five electromagnetic equations:

- **Gauss's law:** Charged particles create an electric field.
- **Faraday's law:** An electric field can also be created by a changing magnetic field.
- **Gauss's law for magnetism:** There are no magnetic monopoles.
- **Ampère-Maxwell law, first half:** Currents create a magnetic field.
- **Ampère-Maxwell law, second half:** A magnetic field can also be created by a changing electric field.
- **Lorentz force law, first half:** An electric force is exerted on a charged particle in an electric field.
- **Lorentz force law, second half:** A magnetic force is exerted on a charge moving in a magnetic field.

These are the *fundamental ideas* of electromagnetism. Other important ideas, such as Ohm's law, Kirchhoff's laws, and Lenz's law, despite their practical importance, are not fundamental ideas. They can be derived from Maxwell's equations, sometimes with the addition of empirically based concepts such as resistance.

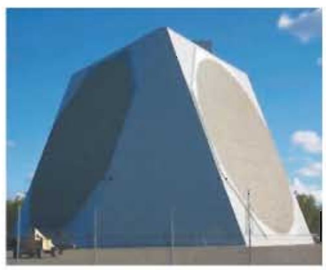
Maxwell's equations can be used to understand motors, generators, antennas and receivers, the transmission of electrical signals through circuits, power lines, microwaves, the electromagnetic properties of materials, and much more. It's true that Maxwell's equations are mathematically more complex than Newton's laws and that their solution, for many problems of practical interest, requires advanced mathematics. Fortunately, we have the mathematical tools to get just far enough into Maxwell's equations to discover their most startling and revolutionary implication—the prediction of electromagnetic waves.

35.5 Electromagnetic Waves

It had been known since the early 19th century, from experiments on interference and diffraction, that light is a wave. We studied the wave properties of light in Part V, but at that time we were not able to determine just what is "waving."

Faraday speculated that light was somehow connected with electricity and magnetism, but Maxwell, using his equations of the electromagnetic field, was the first to understand that light is an oscillation of the electromagnetic field. Maxwell was able to predict that

- Electromagnetic waves can exist at any frequency, not just at the frequencies of visible light. This prediction was the harbinger of radio waves.
- All electromagnetic waves travel in a vacuum with the same speed, a speed that we now call the *speed of light.*



Large radar installations like this one are used to track rockets and missiles.

A general wave equation can be derived from Maxwell's equations, but the necessary mathematical techniques are beyond the level of this textbook. We'll adopt a simpler approach in which we *assume* an electromagnetic wave of a certain form and then show that it's consistent with Maxwell's equations. After all, the wave can't exist *unless* it's consistent with Maxwell's equations.

To begin, we're going to assume that electric and magnetic fields can exist independently of charges and currents in a *source-free* region of space. This is a very important assumption because it makes the statement that **fields are real entities.** They're not just cute pictures that tell us about charges and currents, but real things that can exist all by themselves. Our assertion is that the fields can exist in a self-sustaining mode in which a changing magnetic field creates an electric field (Faraday's law) that in turn

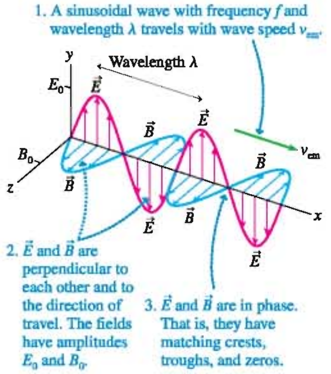


FIGURE 35.19 A sinusoidal electromagnetic wave.

changes in just the right way to re-create the original magnetic field (the Ampère-Maxwell law).

The source-free Maxwell's equations, with no charges or currents, are

$$\oint \vec{E} \cdot d\vec{A} = 0 \qquad \oint \vec{E} \cdot d\vec{s} = -\frac{d\Phi_m}{dt}$$
$$\oint \vec{B} \cdot d\vec{A} = 0 \qquad \oint \vec{B} \cdot d\vec{s} = \epsilon_0 \mu_0 \frac{d\Phi_e}{dt} \tag{35.23}$$

Any electromagnetic wave traveling in empty space must be consistent with these equations.

Let's postulate that an electromagnetic plane wave traveling with speed v_{em} has the characteristics shown in FIGURE 35.19. It's a useful picture, and one that you'll see in any textbook, but a picture that can be very misleading if you don't think about it carefully. $\vec{E}$ and $\vec{B}$ are *not* spatial vectors. That is, they don't stretch spatially in the y- or z-direction for a certain distance. Instead, these vectors are showing the values of the electric and magnetic fields at *points* along a single line, the x-axis. An $\vec{E}$ vector pointing in the y-direction says that *at that point* on the x-axis, where the vector's tail is, the electric field points in the y-direction and has a certain strength. Nothing is "reaching" to a point in space above the x-axis. In fact, this picture contains no information about any points in space other than those right on the x-axis.

However, we are assuming that this is a *plane wave,* which, you'll recall from Chapter 20, is a wave for which the fields are the same at *all points* in any yz-plane, perpendicular to the x-axis. FIGURE 35.20a shows a small section of the xy-plane where, at this instant of time, $\vec{E}$ is pointing up and $\vec{B}$ is pointing toward you. The field strengths vary with x, the direction of travel, but not with y. As the wave moves forward, the fields that are now in the x_1-plane will soon arrive in the x_2-plane, and those now in the x_2-plane will move to x_3.

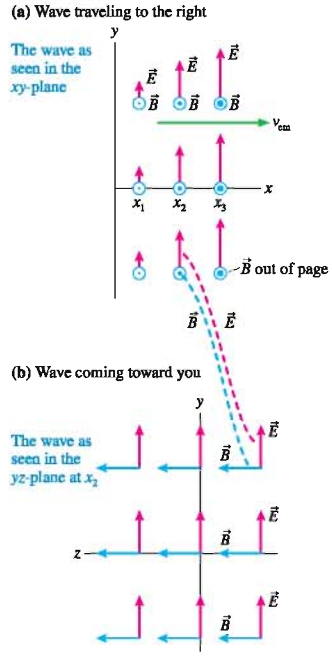

FIGURE 35.20 Interpreting the electromagnetic wave of Figure 35.19.

FIGURE 35.20b shows a section of the yz-plane that slices the x-axis at x_2. These fields are moving out of the page, coming toward you. The fields are the same at *every point* in this plane, which is what we mean by a plane wave. If you watched a movie of the event, you would see the $\vec{E}$ and $\vec{B}$ fields at each point in this plane *oscillating* in time, but always synchronized with all the other points in the plane. Thus you have to use your imagination to see that the $\vec{E}$ and $\vec{B}$ fields in Figure 35.19 are also the $\vec{E}$ and $\vec{B}$ fields *everywhere* in any yz-plane.

Gauss's Laws

Now that we understand the shape of the electromagnetic field, we can check its consistency with Maxwell's equations. This field is a sinusoidal wave, so the components of the fields are

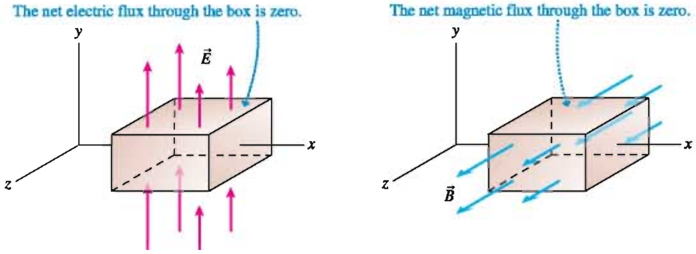
$$\begin{aligned} &E_x = 0 \qquad E_y = E_0 \sin\big(2\pi(x/\lambda - ft)\big) \qquad E_z = 0 \\ &B_x = 0 \qquad B_y = 0 \qquad B_z = B_0 \sin\big(2\pi(x/\lambda - ft)\big) \end{aligned} \tag{35.24}$$

where E_0 and B_0 are the amplitudes of the oscillating electric and magnetic fields.

FIGURE 35.21 shows an imaginary box—a Gaussian surface—centered on the x-axis. Both electric and magnetic field vectors exist at each point in space, but the figure shows them separately for clarity. $\vec{E}$ oscillates along the y-axis, so all electric field lines enter and leave the box through the top and bottom surfaces; no electric field lines pass through the sides of the box.

Because this is a plane wave, the magnitude of each electric field vector entering the bottom of the box is exactly matched by the electric field vector leaving the top. The electric flux through the top of the box is equal in magnitude but opposite in sign to the flux through the bottom, and the flux through the sides is zero. Thus the *net* electric flux is $\Phi_e = 0$. There is no charge inside the box because there are no sources in this region of space, so we also have $Q_{in} = 0$. Hence the electric field of a plane wave is consistent with the first of the source-free Maxwell's equations, Gauss's law.

FIGURE 35.21 A closed surface can be used to check Gauss's law for the electric and magnetic fields.



The exact same argument applies to the magnetic field. The net magnetic flux is $\Phi_m = 0$; thus the magnetic field is consistent with the second of Maxwell's equations.

Faraday's Law

Faraday's law is concerned with the changing magnetic flux through a closed curve. We'll apply Faraday's law to a narrow rectangle in the xy-plane, shown in FIGURE 35.22, with height h and width Δx. We'll assume Δx to be so small that $\vec{B}$ is essentially constant over the width of the rectangle.

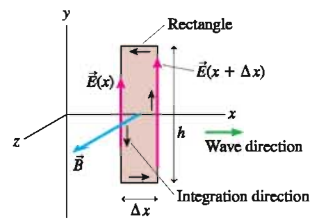


FIGURE 35.22 Faraday's law can be applied to a narrow rectangle in the xy-plane.

The magnetic field $\vec{B}$ points in the z-direction, perpendicular to the rectangle. The magnetic flux through the rectangle is $\Phi_m = B_z A_{\text{rectangle}} = B_z h \Delta x$, hence the flux *changes* at the rate

$$\frac{d\Phi_m}{dt} = \frac{d}{dt}(B_z h \Delta x) = \frac{\partial B_z}{\partial t} h \Delta x \tag{35.25}$$

The ordinary derivative dB_z/dt, which is the full rate of change of B from all possible causes, becomes a partial derivative $\partial B_z/\partial t$ in this situation because the change in magnetic flux is due entirely to the change of B with time and not at all to the spatial variation of B.

According to our sign convention, we have to go around the rectangle in a ccw direction to make the flux positive. Thus we must also use a ccw direction to evaluate the line integral

$$\oint \vec{E} \cdot d\vec{s} = \int_{\text{right}} \vec{E} \cdot d\vec{s} + \int_{\text{top}} \vec{E} \cdot d\vec{s} + \int_{\text{left}} \vec{E} \cdot d\vec{s} + \int_{\text{bottom}} \vec{E} \cdot d\vec{s} \tag{35.26}$$

The electric field $\vec{E}$ points in the y-direction, hence $\vec{E} \cdot d\vec{s} = 0$ at all points on the top and bottom edges, and these two integrals are zero.

Along the left edge of the loop, at position x, $\vec{E}$ has the same value at every point. Figure 35.22a shows that the direction of $\vec{E}$ is *opposite* to $d\vec{s}$, thus $\vec{E} \cdot d\vec{s} = -E_y(x)ds$. On the right edge of the loop, at position $x + \Delta x$, $\vec{E}$ is *parallel* to $d\vec{s}$ and $\vec{E} \cdot d\vec{s} = E_y(x + \Delta x)ds$. Thus the line integral of $\vec{E} \cdot d\vec{s}$ around the rectangle is

$$\oint \vec{E} \cdot d\vec{s} = -E_y(x)h + E_y(x + \Delta x)h = [E_y(x + \Delta x) - E_y(x)]h \tag{35.27}$$

NOTE ▶ $E_y(x)$ indicates that E_y is a function of the position x. It is *not* E_y multiplied by x. ◀

You learned in calculus that the derivative of the function $f(x)$ is

$$\frac{df}{dx} = \lim_{\Delta x \to 0}\left[\frac{f(x + \Delta x) - f(x)}{\Delta x}\right]$$

We've assumed that Δx is very small. If we now let the width of the rectangle go to zero, $\Delta x \to 0$, Equation 35.27 becomes

$$\oint \vec{E} \cdot d\vec{s} = \frac{\partial E_y}{\partial x} h \Delta x \tag{35.28}$$

We've used a partial derivative because E_y is a function of both position x and time t.

Now, using Equations 35.25 and 35.28, we can write Faraday's law as

$$\oint \vec{E} \cdot d\vec{s} = \frac{\partial E_y}{\partial x} h \Delta x = -\frac{d\Phi_m}{dt} = -\frac{\partial B_z}{\partial t} h \Delta x$$

The area $h\Delta x$ of the rectangle cancels, and we're left with

$$\frac{\partial E_y}{\partial x} = -\frac{\partial B_z}{\partial t} \tag{35.29}$$

Equation 35.29, which compares the rate at which E_y varies with position to the rate at which B_z varies with time, is a *required condition* that an electromagnetic wave must satisfy to be consistent with Maxwell's equations. We can use Equation 35.24 for E_y and B_z to evaluate the partial derivatives:

$$\frac{\partial E_y}{\partial x} = \frac{2\pi E_0}{\lambda} \cos\big(2\pi(x/\lambda - ft)\big)$$

$$\frac{\partial B_z}{\partial t} = -2\pi f B_0 \cos\big(2\pi(x/\lambda - ft)\big)$$

Thus the required condition of Equation 35.29 is

$$\frac{\partial E_y}{\partial x} = \frac{2\pi E_0}{\lambda} \cos\big(2\pi(x/\lambda - ft)\big) = -\frac{\partial B_z}{\partial t} = 2\pi f B_0 \cos\big(2\pi(x/\lambda - ft)\big)$$

Canceling the many common factors, and multiplying by λ, we're left with

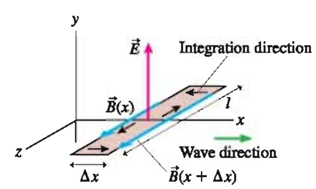
$$E_0 = (\lambda f) B_0 = v_{em} B_0 \tag{35.30}$$

where we used the fact that $\lambda f = v$ for any sinusoidal wave.

Equation 35.30, which came from applying Faraday's law, tells us that the field amplitudes E_0 and B_0 of an electromagnetic wave are not arbitrary. **Once the amplitude B_0 of the magnetic field wave is specified, the electric field amplitude E_0 must be $E_0 = v_{em} B_0$.** Otherwise the fields won't satisfy Maxwell's equations.

The Ampère-Maxwell Law

FIGURE 35.23 The Ampère-Maxwell law can be applied to a narrow rectangle in the xz-plane.



We have one equation to go, but this one will now be easier. The Ampère-Maxwell law is concerned with the changing electric flux through a closed curve. FIGURE 35.23 shows a very narrow rectangle of width Δx and length l in the xz-plane. The electric field is perpendicular to this rectangle; hence the electric flux through it is $\Phi_e = E_y A_{rectangle} = E_y l \Delta x$. This flux is changing at the rate

$$\frac{d\Phi_e}{dt} = \frac{d}{dt}(E_y l \Delta x) = \frac{\partial E_y}{\partial t} l \Delta x \tag{35.31}$$

The line integral of $\vec{B} \cdot d\vec{s}$ around this closed rectangle is calculated just like the line integral of $\vec{E} \cdot d\vec{s}$ in Figure 35.22. $\vec{B}$ is perpendicular to $d\vec{s}$ on the narrow ends, so $\vec{B} \cdot d\vec{s} = 0$. The field at *all* points on the left edge, at position x, is $\vec{B}(x)$, and this field is parallel to $d\vec{s}$ to make $\vec{B} \cdot d\vec{s} = B_z(x)ds$. Similarly, $\vec{B} \cdot d\vec{s} = -B_z(x + \Delta x)ds$ at all points on the right edge, where $\vec{B}$ is opposite to $d\vec{s}$.

Thus, if we let $\Delta x \to 0$,

$$\oint \vec{B} \cdot d\vec{s} = B_z(x)l - B_z(x + \Delta x)l = -[B_z(x + \Delta x) - B_z(x)]l \\ = -\frac{\partial B_z}{\partial x} l \Delta x \tag{35.32}$$

Equations 35.31 and 35.32 can now be used in the Ampère-Maxwell law:

$$\oint \vec{B} \cdot d\vec{s} = -\frac{\partial B_z}{\partial x} l \Delta x = \epsilon_0 \mu_0 \frac{d\Phi_e}{dt} = \epsilon_0 \mu_0 \frac{\partial E_y}{\partial t} l \Delta x$$

The area of the rectangle cancels, and we're left with

$$\frac{\partial B_z}{\partial x} = -\epsilon_0 \mu_0 \frac{\partial E_y}{\partial t} \tag{35.33}$$

Equation 35.33 is a second required condition that the fields must satisfy. If we again evaluate the partial derivatives, using Equation 35.33 for E_y and B_z, we find

$$\frac{\partial E_y}{\partial t} = -2\pi f E_0 \cos\big(2\pi(x/\lambda - ft)\big)$$

$$\frac{\partial B_z}{\partial x} = \frac{2\pi B_0}{\lambda} \cos\big(2\pi(x/\lambda - ft)\big)$$

With these, Equation 35.33 becomes

$$\frac{\partial B_z}{\partial x} = \frac{2\pi B_0}{\lambda} \cos\big(2\pi(x/\lambda - ft)\big) = -\epsilon_0 \mu_0 \frac{\partial E_y}{\partial t} = 2\pi \epsilon_0 \mu_0 f E_0 \cos\big(2\pi(x/\lambda - ft)\big)$$

A final round of cancellations and another use of $\lambda f = v_{em}$ leave us with

$$E_0 = \frac{B_0}{\epsilon_0 \mu_0 \lambda f} = \frac{B_0}{\epsilon_0 \mu_0 v_{em}} \tag{35.34}$$

The last of Maxwell's equations gives us another constraint between E_0 and B_0.

The Speed of Light

But how can Equation 35.30, which required $E_0 = v_{em} B_0$, and Equation 35.34 both be true at the same time? The one and only way is if

$$\frac{1}{\epsilon_0 \mu_0 v_{em}} = v_{em}$$

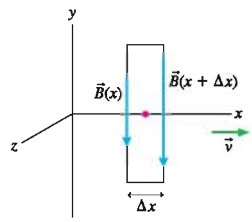
from which we find

$$\boxed{v_{em} = \frac{1}{\sqrt{\epsilon_0 \mu_0}} = 3.00 \times 10^8 \text{ m/s} = c} \tag{35.35}$$

This is a remarkable conclusion. The constants ϵ_0 and μ_0 are from electrostatics and magnetostatics, where they determine the size of $\vec{E}$ and $\vec{B}$ due to point charges. Coulomb's law and the Biot-Savart law, where ϵ_0 and μ_0 first appeared, have nothing to do with waves. Yet Maxwell's theory of electromagnetism ends up predicting that electric and magnetic fields can form a self-sustaining electromagnetic wave *if* that wave travels at the specific speed $v_{em} = 1/\sqrt{\epsilon_0 \mu_0}$. No other speed will satisfy Maxwell's equations.

We've made no assumption about the frequency of the wave, so apparently all electromagnetic waves, regardless of their frequency, travel (in vacuum) at the same speed $v_{em} = 1/\sqrt{\epsilon_0 \mu_0}$. We call this speed c, the "speed of light," but it applies equally well from low-frequency radio waves to ultrahigh-frequency x rays.

STOP TO THINK 35.5 An electromagnetic wave is propagating in the positive x-direction. At this instant of time, what is the direction of $\vec{E}$ at the center of the rectangle?



a. In the positive x-direction
b. In the negative x-direction
c. In the positive y-direction
d. In the negative y-direction
e. In the positive z-direction
f. In the negative z-direction

35.6 Properties of Electromagnetic Waves

We've demonstrated that one very specific sinusoidal wave is consistent with Maxwell's equations. It's possible to show that *any* electromagnetic wave, whether it's sinusoidal or not, must satisfy four basic conditions:

1. The fields $\vec{E}$ and $\vec{B}$ are perpendicular to the direction of propagation $\vec{v}_{em}$. Thus an electromagnetic wave is a transverse wave.
2. $\vec{E}$ and $\vec{B}$ are perpendicular to each other in a manner such that $\vec{E} \times \vec{B}$ is in the direction of $\vec{v}_{em}$.
3. The wave travels in vacuum at speed $v_{em} = 1/\sqrt{\epsilon_0\mu_0} = c$.
4. $E = cB$ at any point on the wave.

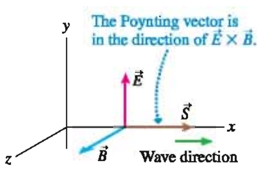
In this section, we'll look at some other properties of electromagnetic waves.

Energy and Intensity

Waves transfer energy. Ocean waves erode beaches, sound waves set your eardrum vibrating, and light from the sun warms the earth. The energy flow of an electromagnetic wave is described by the **Poynting vector** $\vec{S}$, defined as

$$\vec{S} \equiv \frac{1}{\mu_0}\vec{E} \times \vec{B} \tag{35.36}$$

FIGURE 35.24 The Poynting vector.



The Poynting vector, shown in **FIGURE 35.24**, has two important properties:

1. At any point, the Poynting vector points in the direction in which an electromagnetic wave is traveling. You can see this by looking back at Figure 35.19.
2. The magnitude S of the Poynting vector measures the rate of energy transfer per unit area of the wave. As a homework problem, you can show that the units of S are W/m^2, or power (joules per second) per unit area.

Because $\vec{E}$ and $\vec{B}$ of an electromagnetic wave are perpendicular to each other, and $E = cB$, the magnitude of the Poynting vector is

$$S = \frac{EB}{\mu_0} = \frac{E^2}{c\mu_0}$$

The Poynting vector is a function of time, oscillating from zero to $S_{max} = E_0^2/c\mu_0$ and back to zero twice during each period of the wave's oscillation. That is, the energy flow in an electromagnetic wave is not smooth. It "pulses" as the electric and magnetic fields oscillate in intensity. We're unaware of this pulsing because the electromagnetic waves that we can sense—light waves—have such high frequencies.

Of more interest is the *average* energy transfer, averaged over one cycle of oscillation, which is the wave's **intensity** I. In our earlier study of waves, we defined the intensity of a wave to be $I = P/A$, where P is the power (energy transferred per second)

of a wave that impinges on area A. Because $E = E_0 \sin(2\pi(x/\lambda - ft))$, and the average over one period of $\sin^2(2\pi(x/\lambda - ft))$ is $\frac{1}{2}$, the intensity of an electromagnetic wave is

$$I = \frac{P}{A} = S_{avg} = \frac{1}{2c\mu_0}E_0^2 = \frac{c\epsilon_0}{2}E_0^2 \qquad (35.37)$$

Equation 35.37 relates the intensity of an electromagnetic wave, a quantity that is easily measured, to the amplitude of the wave's electric field.

EXAMPLE 35.4 The electric field of a laser beam

A helium-neon laser, the laser commonly used for classroom demonstrations, emits a 1.0-mm-diameter laser beam with a power of 1.0 mW. What is the amplitude of the oscillating electric field in the laser beam?

MODEL The laser beam is an electromagnetic plane wave.

SOLVE 1.0 mW, or 1.0×10^{-3} J/s, is the energy transported per second by the light wave. This energy is carried within a 1.0-mm-diameter beam, so the light intensity is

$$I = \frac{P}{A} = \frac{P}{\pi r^2} = \frac{1.0 \times 10^{-3}\ \text{W}}{\pi(0.00050\ \text{m})^2} = 1270\ \text{W/m}^2$$

We can use Equation 35.37 to relate this intensity to the electric field amplitude:

$$E_0 = \sqrt{\frac{2I}{c\epsilon_0}} = \sqrt{\frac{2(1270\ \text{W/m}^2)}{(3.00 \times 10^8\ \text{m/s})(8.85 \times 10^{-12}\ \text{C}^2/\text{Nm}^2)}}$$
$$= 980\ \text{V/m}$$

ASSESS This is a sizable electric field, comparable to the electric field near a charged glass or plastic rod.

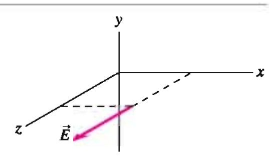
The intensity of a plane wave, with constant electric field amplitude E_0, would not change with distance. But a plane wave is an idealization; there are no true plane waves in nature. You learned in Chapter 20 that, to conserve energy, the intensity of a wave far from its source decreases with the inverse square of the distance. If a source with power P_{source} emits electromagnetic waves *uniformly* in all directions, the electromagnetic wave intensity at distance r from the source is

$$I = \frac{P_{source}}{4\pi r^2} \qquad (35.38)$$

Equation 35.38 simply expresses the recognition that the energy of the wave is spread over a sphere of surface area $4\pi r^2$.

STOP TO THINK 35.4 An electromagnetic wave is traveling in the positive y-direction. The electric field at one instant of time is shown at one position. The magnetic field at this position points

a. In the positive x-direction.
b. In the negative x-direction.
c. In the positive y-direction.
d. In the negative y-direction.
e. Toward the origin.
f. Away from the origin.



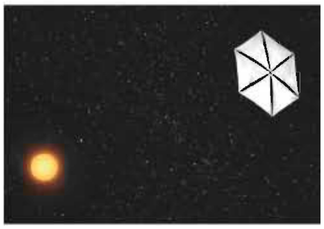
Radiation Pressure

Electromagnetic waves transfer not only energy but also momentum. An object gains momentum when it absorbs electromagnetic waves, much as a ball at rest gains momentum when struck by a ball in motion.

Suppose we shine a beam of light on an object that completely absorbs the light energy. If the object absorbs energy during a time interval Δt, its momentum changes by

$$\Delta p = \frac{\text{energy absorbed}}{c}$$

This is a consequence of Maxwell's theory, which we'll state without proof.



Artist's conception of a future spacecraft powered by radiation pressure from the sun.

The momentum change implies that the light is exerting a force on the object. Newton's second law, in terms of momentum, is $F = \Delta p/\Delta t$. The radiation force due to the beam of light is

$$F = \frac{\Delta p}{\Delta t} = \frac{(\text{energy absorbed})/\Delta t}{c} = \frac{P}{c}$$

where P is the power (joules per second) of the light.

It's more interesting to consider the force exerted on an object per unit area, which is called the **radiation pressure** p_{rad}. The radiation pressure on an object that absorbs all the light is

$$p_{rad} = \frac{F}{A} = \frac{P/A}{c} = \frac{I}{c} \tag{35.39}$$

where I is the intensity of the light wave. The subscript on p_{rad} is important in this context to distinguish the radiation pressure from the momentum p.

EXAMPLE 35.5 Solar sailing

A low-cost way of sending spacecraft to other planets would be to use the radiation pressure on a solar sail. The intensity of the sun's electromagnetic radiation at distances near the earth's orbit is about 1300 W/m^2. What size sail would be needed to accelerate a 10,000 kg spacecraft toward Mars at 0.010 m/s^2?

MODEL Assume that the solar sail is perfectly absorbing.

SOLVE The force that will create a 0.010 m/s^2 acceleration is $F = ma = 100$ N. We can use Equation 35.39 to find the sail area that, by absorbing light, will receive a 100 N force from the sun:

$$A = \frac{cF}{I} = \frac{(3.00 \times 10^8 \text{ m/s})(100 \text{ N})}{1300 \text{ W/m}^2} = 2.3 \times 10^7 \text{ m}^2$$

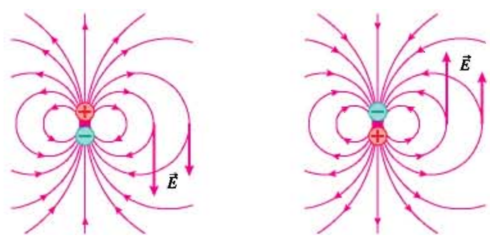
ASSESS If the sail is a square, it would need to be 4.8 km $\times$ 4.8 km, or roughly 3 mi $\times$ 3 mi. This is large, but not entirely out of the question with thin films that can be unrolled in space. But how will the crew return from Mars?

Antennas

We've seen that an electromagnetic wave is self-sustaining, independent of charges or currents. However, charges and currents are needed at the *source* of an electromagnetic wave. We'll take a brief look at how an electromagnetic wave is generated by an antenna.

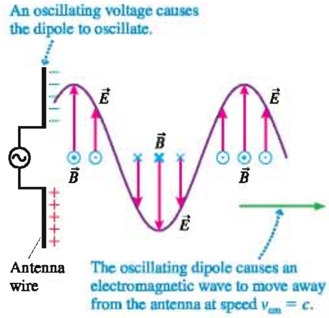
FIGURE 35.25 is the electric field of an electric dipole. If the dipole is vertical, the electric field $\vec{E}$ at points along a horizontal line is also vertical. Reversing the dipole, by switching the charges, reverses $\vec{E}$. If the charges were to oscillate back and forth, switching position at frequency f, then $\vec{E}$ would oscillate in a vertical plane. The changing $\vec{E}$ would then create an induced magnetic field $\vec{B}$, which could then create an $\vec{E}$, which could then create a $\vec{B}$, . . . , and an electromagnetic wave at frequency f would radiate out into space.

FIGURE 35.25 An electric dipole creates an electric field that reverses direction if the dipole charges are switched.



This is exactly what an **antenna** does. FIGURE 35.26 shows two metal wires attached to the terminals of an oscillating voltage source. The figure shows an instant when the top wire is negative and the bottom is positive, but these will reverse in half a cycle. The wire is basically an oscillating dipole, and it creates an oscillating electric field. The oscillating $\vec{E}$ induces an oscillating $\vec{B}$, and they take off as an electromagnetic wave at speed $v_{em} = c$. The wave does need oscillating charges as a *wave source*, but once created it is self-sustaining and independent of the source. The antenna might be destroyed, but the wave could travel billions of light years across the universe, bearing the legacy of James Clerk Maxwell.

FIGURE 35.26 An antenna generates a self-sustaining electromagnetic wave.



STOP TO THINK 35.5 The amplitude of the oscillating electric field at your cell phone is 4.0 μV/m when you are 10 km east of the broadcast antenna. What is the electric field amplitude when you are 20 km east of the antenna?

a. 1.0 μV/m
b. 2.0 μV/m
c. 4.0 μV/m
d. There's not enough information to tell.

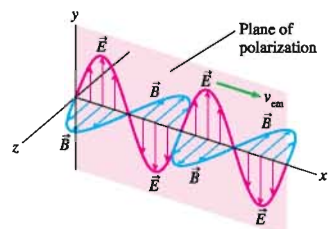
35.7 Polarization

The plane of the electric field vector $\vec{E}$ and the Poynting vector $\vec{S}$ (the direction of propagation) is called the **plane of polarization** of an electromagnetic wave. Figure 35.27 shows two electromagnetic waves moving along the x-axis. The electric field in FIGURE 35.27a oscillates vertically, so we would say that this wave is *vertically polarized.* Similarly the wave in FIGURE 35.27b is *horizontally polarized.* Other polarizations are possible, such as a wave polarized 30° away from horizontal.

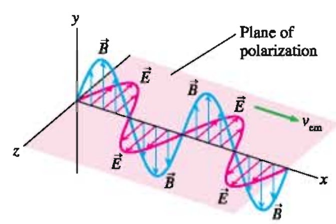
NOTE ▶ This use of the term "polarization" is completely independent of the idea of *charge polarization* that you learned about in Chapter 26. ◀

FIGURE 35.27 The plane of polarization is the plane in which the electric field vector oscillates.

(a) Vertical polarization



(b) Horizontal polarization



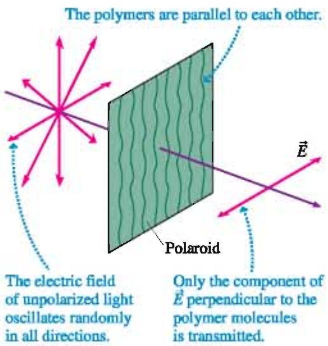
Some wave sources, such as lasers and radio antennas, emit *polarized* electromagnetic waves with a well-defined plane of polarization. By contrast, most natural sources of electromagnetic radiation are unpolarized. Each atom in the sun's hot atmosphere emits light independently of all the other atoms, as does each tiny piece of metal in the incandescent filament of a lightbulb. An electromagnetic wave that you see or measure is a superposition of waves from each of these tiny emitters. Although the wave from each individual emitter is polarized, it is polarized in a random direction with respect to the waves from all its neighbors. The net result is what we call an *unpolarized* wave, a wave whose electric field oscillates randomly with all possible orientations.

A few natural sources are *partially polarized,* meaning that one direction of polarization is more prominent than others. The light of the sky at right angles to the sun is partially polarized because of how the sun's light scatters from air molecules to create skylight. Bees and other insects make use of this partial polarization to navigate. Light reflected from a flat, horizontal surface, such as a road or the surface of a lake, has a predominantly horizontal polarization. This is the rationale for using polarizing sunglasses.

ActivPhysics ONLINE 16.9

The most common way of artificially generating polarized visible light is to send unpolarized light through a *polarizing filter.* The first widely used polarizing filter was invented by Edwin Land in 1928, while he was still an undergraduate student. He

FIGURE 35.28 A polarizing filter.



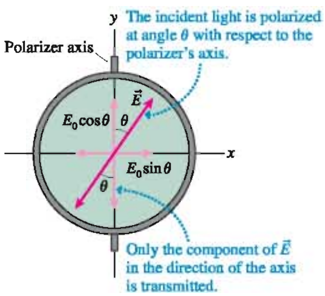
developed an improved version, called Polaroid, in 1938. Polaroid, as shown in FIGURE 35.28, is a plastic sheet containing very long organic molecules known as polymers. The sheets are formed in such a way that the polymers are all aligned to form a grid, rather like the metal bars in a barbecue grill. The sheet is then chemically treated to make the polymer molecules somewhat conducting.

As a light wave travels through Polaroid, the component of the electric field oscillating parallel to the polymer grid drives the conduction electrons up and down the molecules. The electrons absorb energy from the light wave, so the parallel component of $\vec{E}$ is absorbed in the filter. But the conduction electrons can't oscillate perpendicular to the molecules, so the component of $\vec{E}$ perpendicular to the polymer grid passes through without absorption. Thus the light wave emerging from a polarizing filter is polarized perpendicular to the polymer grid.

Malus's Law

Suppose a *polarized* light wave of intensity I_0 approaches a polarizing filter. What is the intensity of the light that passes through the filter? FIGURE 35.29 shows that an oscillating electric field can be decomposed into components parallel and perpendicular to the polarizer's axis (i.e., the polarization direction transmitted by the polarizer). If we call the polarizer axis the y-axis, then the incident electric field is

FIGURE 35.29 An incident electric field can be decomposed into components parallel and perpendicular to a polarizer's axis.



$$\vec{E}_{\text{incident}} = E_\perp\hat{\imath} + E_\parallel\hat{\jmath} = E_0\sin\theta\,\hat{\imath} + E_0\cos\theta\,\hat{\jmath} \tag{35.40}$$

where θ is the angle between the incident plane of polarization and the polarizer axis.

If the polarizer is ideal, meaning that light polarized parallel to the axis is 100% transmitted and light perpendicular to the axis is 100% blocked, then the electric field of the light transmitted by the filter is

$$\vec{E}_{\text{transmitted}} = E_\parallel\hat{\jmath} = E_0\cos\theta\,\hat{\jmath} \tag{35.41}$$

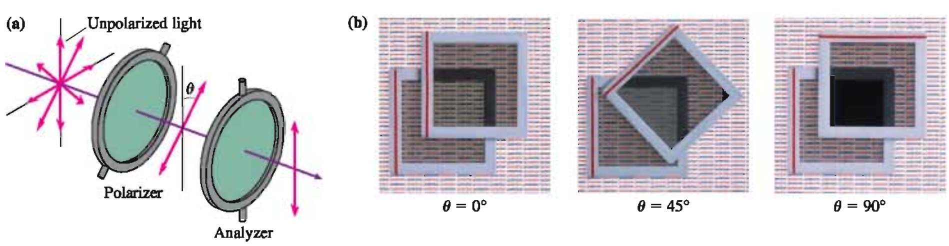
Because the intensity depends on the square of the electric field amplitude, you can see that the transmitted intensity is related to the incident intensity by

$$I_{\text{transmitted}} = I_0\cos^2\theta \qquad \text{(incident light polarized)} \tag{35.42}$$

This result, which was discovered experimentally in 1809, is called **Malus's law.**

FIGURE 35.30a shows that Malus's law can be demonstrated with two polarizing filters. The first, called the *polarizer,* is used to produce polarized light of intensity I_0. The second, called the *analyzer,* is rotated by angle θ relative to the polarizer. As the photographs of FIGURE 35.30b show, the transmission of the analyzer is (ideally) 100% when $\theta = 0°$ and steadily decreases to zero when $\theta = 90°$. Two polarizing filters with perpendicular axes, called *crossed polarizers,* block all the light.

FIGURE 35.30 The intensity of the transmitted light depends on the angle between the polarizing filters.



Suppose the light incident on a polarizing filter is *unpolarized,* as is the light incident from the left on the polarizer in Figure 35.30a. The electric field of unpolarized light varies randomly through all possible values of θ. Because the ***average*** value of $\cos^2\theta$ is $\frac{1}{2}$, the intensity transmitted by a polarizing filter is

$$I_{\text{transmitted}} = \frac{1}{2}I_0 \qquad \text{(incident light unpolarized)} \qquad (35.43)$$

In other words, a polarizing filter passes 50% of unpolarized light and blocks 50%.

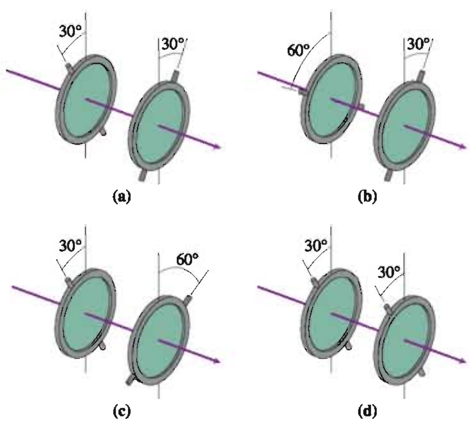
In polarizing sunglasses, the polymer grid is aligned horizontally (when the glasses are in the normal orientation) so that the glasses transmit vertically polarized light. Most natural light is unpolarized, so the glasses reduce the light intensity by 50%. But *glare*—the reflection of the sun and the skylight from roads and other horizontal surfaces—has a strong horizontal polarization. This light is almost completely blocked by the Polaroid, so the sunglasses "cut glare" without affecting the main scene you wish to see.

You can test whether your sunglasses are polarized by holding them in front of you and rotating them as you look at the glare reflecting from a horizontal surface. Polarizing sunglasses substantially reduce the glare when the glasses are "normal" but not when the glasses are 90° from normal. (You can also test them against a pair of sunglasses known to be polarizing by seeing if all light is blocked when the lenses of the two pairs are crossed.)

If you have polarizing sunglasses, look at the sky about 90° from the sun in the early morning or late afternoon. You can detect the sky's polarization by rotating the glasses. Bees can automatically sense the polarization of skylight, but humans can't.

The vertical polarizer blocks the horizontally polarized glare from the surface of the water.

STOP TO THINK 35.6 Unpolarized light of equal intensity is incident on four pairs of polarizing filters. Rank in order, from largest to smallest, the intensities I_a to I_d transmitted through the second polarizer of each pair.



SUMMARY

The goal of Chapter 35 has been to study the properties of electromagnetic fields and waves.

General Principles

Maxwell's Equations

These equations govern electromagnetic fields:

$\oint \vec{E} \cdot d\vec{A} = \dfrac{Q_{in}}{\epsilon_0}$	Gauss's law
$\oint \vec{B} \cdot d\vec{A} = 0$	Gauss's law for magnetism
$\oint \vec{E} \cdot d\vec{s} = -\dfrac{d\Phi_m}{dt}$	Faraday's law
$\oint \vec{B} \cdot d\vec{s} = \mu_0 I_{through} + \epsilon_0\mu_0 \dfrac{d\Phi_e}{dt}$	Ampère-Maxwell law

Maxwell's equations tell us that:

An electric field can be created by
- Charged particles
- A changing magnetic field

A magnetic field can be created by
- A current
- A changing electric field

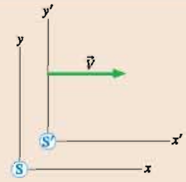
Lorentz Force

This force law governs the interaction of charged particles with electromagnetic fields:

$$\vec{F} = q(\vec{E} + \vec{v} \times \vec{B})$$

- An electric field exerts a force on any charged particle.
- A magnetic field exerts a force on a moving charged particle.

Field Transformations



Fields measured in frame S to be $\vec{E}$ and $\vec{B}$ are found in frame S' to be

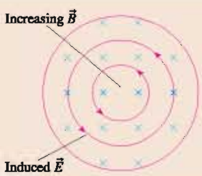
$$\vec{E}' = \vec{E} + \vec{V} \times \vec{B}$$

$$\vec{B}' = \vec{B} - \frac{1}{c^2}\vec{V} \times \vec{E}$$

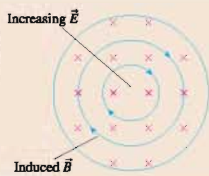
Important Concepts

Induced fields

An induced electric field is created by a changing magnetic field.



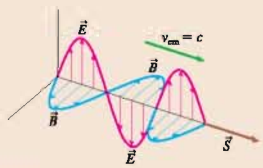
An induced magnetic field is created by a changing electric field.



These fields can exist independently of charges and currents.

An electromagnetic wave is a self-sustaining electromagnetic field.

- An em wave is a transverse wave with $\vec{E}$, $\vec{B}$, and $\vec{v}$ mutually perpendicular.
- An em wave propagates with speed $v_{em} = c = 1/\sqrt{\epsilon_0\mu_0}$.
- The electric and magnetic field strengths are related by $E = cB$.
- The **Poynting vector** $\vec{S} = (\vec{E} \times \vec{B})/\mu_0$ is the energy transfer in the direction of travel.
- The wave **intensity** is $I = P/A = (1/2c\mu_0)E_0^2 = (c\epsilon_0/2)E_0^2$.



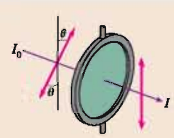
Applications

Polarization

The electric field and the Poynting vector define the **plane of polarization.** The intensity of polarized light transmitted through a polarizing filter is given by Malus's law:

$$I = I_0\cos^2\theta$$

where θ is the angle between the electric field and the polarizer axis.



Terms and Notation

Galilean field transformation equations	Poynting vector, $\vec{S}$	antenna
displacement current	intensity, I	plane of polarization
Maxwell's equations	radiation pressure, p_{rad}	Malus's law

Problems labeled ▢ integrate significant material from earlier chapters.

CONCEPTUAL QUESTIONS

1. Andre is flying his spaceship to the left through the laboratory magnetic field of FIGURE Q35.1.
   a. Does Andre see a magnetic field? If so, in which direction does it point?
   b. Does Andre see an electric field? If so, in which direction does it point?

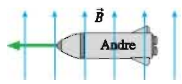

FIGURE Q35.1

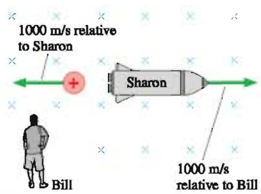

FIGURE Q35.2

2. Sharon drives her rocket through the magnetic field of FIGURE Q35.2, traveling to the right at a speed of 1000 m/s as measured by Bill. As she passes Bill, she shoots a positive charge backward at a speed of 1000 m/s relative to her.
   a. According to Sharon, what kind of force or forces act on the charge? In which directions? Explain.
   b. According to Bill, what kind of force or forces act on the charge? In which directions? Explain.
3. If you curl the fingers of your right hand as shown, are the electric fluxes in FIGURE Q35.3 positive or negative?

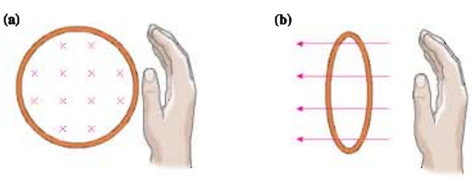

FIGURE Q35.3

4. What is the current through surface S in FIGURE Q35.4 if you curl your right fingers in the direction of the arrow?

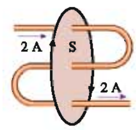

FIGURE Q35.4

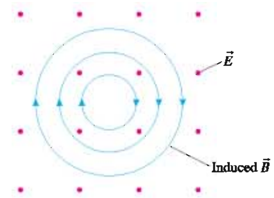

FIGURE Q35.5

5. Is the electric field strength in FIGURE Q35.5 increasing, decreasing, or not changing? Explain.
6. Do the situations in FIGURE Q35.6 represent possible electromagnetic waves? If not, why not?

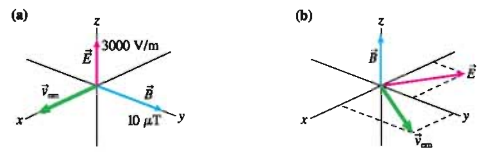

FIGURE Q35.6

7. In what directions are the electromagnetic waves traveling in FIGURE Q35.7?

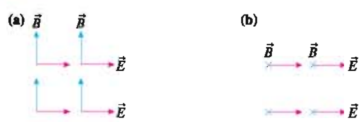

FIGURE Q35.7

8. The intensity of an electromagnetic wave is 10 W/m^2. What will the intensity be if:
   a. The amplitude of the electric field is doubled?
   b. The amplitude of the magnetic field is doubled?
   c. The amplitudes of both the electric and the magnetic field are doubled?
   d. The frequency is doubled?

9. Older televisions used a *loop antenna* like the one in FIGURE Q35.9. How does this antenna work?

FIGURE Q35.9

10. A vertically polarized electromagnetic wave passes through the five polarizers in FIGURE Q35.10. Rank in order, from largest to smallest, the transmitted intensities I_a to I_e.

EXERCISES AND PROBLEMS

Exercises

Section 35.1 E or B? It Depends on Your Perspective

1. || A rocket cruises past a laboratory at 1.00×10^6 m/s in the positive x-direction just as a proton is launched with velocity (in the laboratory frame) $\vec{v} = (1.41 \times 10^6\hat{\imath} + 1.41 \times 10^6\hat{\jmath})$ m/s. What are the proton's speed and its angle from the y-axis (or y'-axis) in (a) the laboratory frame and (b) the rocket frame?

2. | FIGURE EX35.2 shows the electric and magnetic field in frame S. A rocket travels parallel to one of the axes of the S coordinate system. Along which axis must the rocket travel, and in which direction (or directions), in order for the rocket scientists to measure (a) $B' > B$, (b) $B' = B$, and (c) $B' < B$?

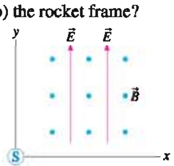

FIGURE EX35.2

3. || Scientists in the laboratory create a uniform electric field $\vec{E} = -1.0 \times 10^6\hat{\jmath}$ V/m in a region of space where $\vec{B} = \vec{0}$. What are the fields in the reference frame of a rocket traveling in the positive x-direction at 1.0×10^6 m/s?

4. | A rocket zooms past the earth at $v = 2.0 \times 10^6$ m/s. Scientists on the rocket have created the electric and magnetic fields shown in FIGURE EX35.4. What are the fields measured by an earthbound scientist?

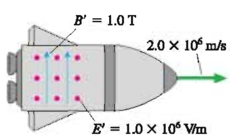

FIGURE EX35.4

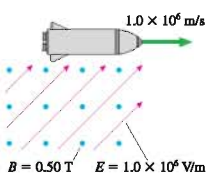

FIGURE EX35.5

5. || Laboratory scientists have created the electric and magnetic fields shown in FIGURE EX35.5. These fields are also seen by scientists that zoom past in a rocket traveling in the x-direction at 1.0×10^6 m/s. According to the rocket scientists, what angle does the electric field make with the axis of the rocket?

Section 35.2 The Field Laws Thus Far

Section 35.3 The Displacement Current

6. | The magnetic field is uniform over each face of the box shown in FIGURE EX35.6. What are the magnetic field strength and direction on the front surface?

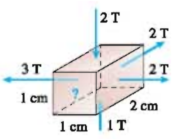

FIGURE EX35.6

7. | Show that the quantity $\epsilon_0(d\Phi_e/dt)$ has units of current.

8. || Show that the displacement current inside a parallel-plate capacitor can be written $C(dV_C/dt)$.

9. || At what rate must the potential difference increase across a 1.0 μF capacitor to create a 1.0 A displacement current in the capacitor?

10. || A 10-cm-diameter parallel-plate capacitor has a 1.0 mm spacing. The electric field between the plates is increasing at the rate 1.0×10^6 V/m s. What is the magnetic field strength (a) on the axis, (b) 3.0 cm from the axis, and (c) 7.0 cm from the axis?

11. || A square parallel-plate capacitor 5.0 cm on a side has a 0.50 mm gap. What is the displacement current in the capacitor if the potential difference across the capacitor is increasing at 500,000 V/s?

Section 35.5 Electromagnetic Waves

12. | What is the magnetic field amplitude of an electromagnetic wave whose electric field amplitude is 10 V/m?

13. | What is the electric field amplitude of an electromagnetic wave whose magnetic field amplitude is 2.0 mT?

14. | The magnetic field of an electromagnetic wave in a vacuum is $B_z = (3.00\ \mu\text{T})\sin((1.00 \times 10^7)x - \omega t)$, where x is in m and t is in s. What are the wave's (a) wavelength, (b) frequency, and (c) electric field amplitude?

15. || The electric field of an electromagnetic wave in a vacuum is $E_y = (20.0\ \text{V/m})\cos((6.28 \times 10^8)x - \omega t)$, where x is in m and t is in s. What are the wave's (a) wavelength, (b) frequency, and (c) magnetic field amplitude?

Section 35.6 Properties of Electromagnetic Waves

16. | A radio wave is traveling in the negative y-direction. What is the direction of $\vec{E}$ at a point where $\vec{B}$ is in the positive x-direction?

17. | Show that:
   a. The quantity cB has the same units as E.
   b. The Poynting vector has units W/m^2.

18. | a. What is the magnetic field amplitude of an electromagnetic wave whose electric field amplitude is 100 V/m?
   b. What is the intensity of the wave?

19. || A radio receiver can detect signals with electric field amplitudes as small as 300 μV/m. What is the intensity of the smallest detectable signal?

20. || A 200 MW laser pulse is focused with a lens to a diameter of 2.0 μm.
   a. What is the laser beam's electric field amplitude at the focal point?
   b. What is the ratio of the laser beam's electric field to the electric field that keeps the electron bound to the proton of a hydrogen atom?

21. | A radio antenna broadcasts a 1.0 MHz radio wave with 25 kW of power. Assume that the radiation is emitted uniformly in all directions.
   a. What is the wave's intensity 30 km from the antenna?
   b. What is the electric field amplitude at this distance?

22. || At what distance from a 10 W point source of electromagnetic waves is the electric field amplitude (a) 100 V/m and (b) 0.010 V/m?

23. | A 1000 W carbon-dioxide laser emits light with a wavelength of 10 μm into a 3.0-mm-diameter laser beam. What force does the laser beam exert on a completely absorbing target?

Section 35.7 Polarization

24. || FIGURE EX35.24 shows a vertically polarized radio wave of frequency 1.0×10^6 Hz traveling into the page. The maximum electric field strength is 1000 V/m. What are
   a. The maximum magnetic field strength?
   b. The magnetic field strength and direction at a point where $\vec{E} =$ (500 V/m, down)?
   c. The smallest distance between a point on the wave having the magnetic field of part b and a point where the magnetic field is at maximum strength?

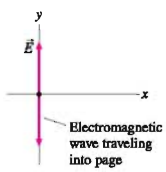

FIGURE EX35.24

25. || Only 25% of the intensity of a polarized light wave passes through a polarizing filter. What is the angle between the electric field and the axis of the filter?

26. || A 200 mW horizontally polarized laser beam passes through a polarizing filter whose axis is 25° from vertical. What is the power of the laser beam as it emerges from the filter?

27. || Unpolarized light with intensity 350 W/m^2 passes first through a polarizing filter with its axis vertical, then through a polarizing filter with its axis 30° from vertical. What light intensity emerges from the second filter?

Problems

28. || What is the force (magnitude and direction) on the proton in FIGURE P35.28? Give the direction as an angle cw or ccw from the positive y-axis.

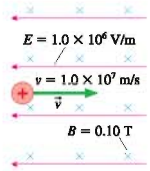

FIGURE P35.28

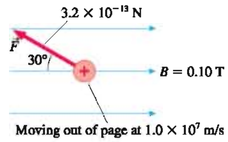

FIGURE P35.29

29. | What are the electric field strength and direction at the position of the proton in FIGURE P35.29?

30. | What electric field strength and direction will allow the electron in FIGURE P35.30 to pass through this region of space without being deflected?

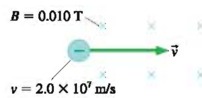

FIGURE P35.30

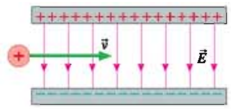

FIGURE P35.31

31. || A proton is fired with a speed of 1.0×10^6 m/s through the parallel-plate capacitor shown in FIGURE P35.31. The capacitor's electric field is $\vec{E} = (1.0 \times 10^5$ V/m, down).
   a. What magnetic field $\vec{B}$, both strength and direction, must be applied to allow the proton to pass through the capacitor with no change in speed or direction?
   b. Find the electric and magnetic fields in the proton's reference frame.
   c. How does an experimenter in the proton's frame explain that the proton experiences no force as the charged plates fly by?

32. ||| An electron travels with $\vec{v} = 5.0 \times 10^6 \hat{\imath}$ m/s through a point in space where $\vec{E} = (2.0 \times 10^5 \hat{\imath} - 2.0 \times 10^5 \hat{\jmath})$ V/m and $\vec{B} = -0.10\hat{k}$ T. What is the force on the electron?

33. || A very long, 1.0-mm-diameter wire carries a 2.5 A current from left to right. Thin plastic insulation on the wire is positively charged with linear charge density 2.5 nC/cm. A mosquito 1.0 cm from the center of the wire would like to move in such a way as to experience an electric field but no magnetic field. How fast and which direction should she fly?

34. || In FIGURE P35.34, a circular loop of radius r travels with speed v along a charged wire having linear charge density λ. The wire is at rest in the laboratory frame, and it passes through the center of the loop.

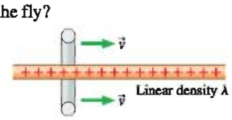

FIGURE P35.34

   a. What are $\vec{E}$ and $\vec{B}$ at a point on the loop as measured by a scientist in the laboratory? Include both strength and direction.
   b. What are the fields $\vec{E}'$ and $\vec{B}'$ at a point on the loop as measured by a scientist in the frame of the loop?
   c. Show that an experimenter in the loop's frame sees a current $I = \lambda v$ passing through the center of the loop.
   d. What electric and magnetic fields would an experimenter in the loop's frame calculate at distance r from the current of part c?
   e. Show that your fields of parts b and d are the same.
   f. If the loop is made of a conducting material, will it have an induced current? Explain.

35. || The magnetic field inside a 4.0-cm-diameter superconducting solenoid varies sinusoidally between 8.0 T and 12.0 T at a frequency of 10 Hz.
  a. What is the maximum electric field strength at a point 1.5 cm from the solenoid axis?
  b. What is the value of B at the instant E reaches its maximum value?

36. || A simple series circuit consists of a 150 Ω resistor, a 25 V battery, a switch, and a 2.5 pF parallel-plate capacitor (initially uncharged) with plates 5.0 mm apart. The switch is closed at $t = 0$ s.
  a. After the switch is closed, find the maximum electric flux and the maximum displacement current through the capacitor.
  b. Find the electric flux and the displacement current at $t = 0.50$ ns.

37. || A wire with conductivity σ carries current I. The current is increasing at the rate dI/dt.
  a. Show that there is a displacement current in the wire equal to $(\epsilon_0/\sigma)(dI/dt)$.
  b. Evaluate the displacement current for a copper wire in which the current is increasing at 1.0×10^6 A/s.

38. || A 10 A current is charging a 1.0-cm-diameter parallel-plate capacitor.
  a. What is the magnetic field strength at a point 2.0 mm from the center of the wire leading to the capacitor?
  b. What is the magnetic field strength at a point 2.0 mm from the center of the capacitor?

39. || FIGURE P35.39 shows the voltage across a 0.10 μF capacitor. Draw a graph showing the displacement current through the capacitor as a function of time.

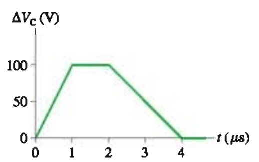

FIGURE P35.39

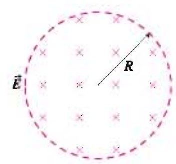

FIGURE P35.40

40. || FIGURE P35.40 shows the electric field inside a cylinder of radius $R = 3.0$ mm. The field strength is increasing with time as $E = 1.0 \times 10^8 t^2$ V/m, where t is in s. The electric field outside the cylinder is always zero, and the field inside the cylinder was zero for $t < 0$.
  a. Find an expression for the electric flux Φ_e through the entire cylinder as a function of time.
  b. Draw a picture showing the magnetic field lines inside and outside the cylinder. Be sure to include arrowheads showing the field's direction.
  c. Find an expression for the magnetic field strength as a function of time at a distance $r < R$ from the center. Evaluate the magnetic field strength at $r = 2.0$ mm, $t = 2.0$ s.
  d. Find an expression for magnetic field strength as a function of time at a distance $r > R$ from the center. Evaluate the magnetic field strength at $r = 4.0$ mm, $t = 2.0$ s.

41. || At one instant, the electric and magnetic fields at one point of an electromagnetic wave are $\vec{E} = (200\hat{\imath} + 300\hat{\jmath} - 50\hat{k})$ V/m and $\vec{B} = B_0(7.3\hat{\imath} - 7.3\hat{\jmath} + a\hat{k})$ μT.
  a. What are the values of a and B_0?
  b. What is the Poynting vector at this time and position?

42. || a. Show that u_E and u_B, the energy densities of the electric and magnetic fields, are equal to each other in an electromagnetic wave. In other words, show that the wave's energy is divided equally between the electric field and the magnetic field.
  b. What is the total energy density in an electromagnetic wave of intensity 1000 W/m^2?

43. || Assume that a 100 W lightbulb radiates all its energy as a single wavelength of visible light. Estimate the electric and magnetic field strengths at the surface of the bulb.

44. || The intensity of sunlight reaching the earth is 1360 W/m^2.
  a. What is the power output of the sun?
  b. What is the intensity of sunlight on Mars?

45. || A cube of water 10 cm on a side is placed in a microwave beam having $E_0 = 11$ kV/m. The microwaves illuminate one face of the cube, and the water absorbs 80% of the incident energy. How long will it take to raise the water temperature by 50°C? Assume that the water has no heat loss during this time.

46. || A laser beam passes through a converging lens with a focal length of 10 cm. At what distance past the lens has the laser beam's (a) intensity and (b) electric field strength increased by a factor of 4?

47. | When the Voyager 2 spacecraft passed Neptune in 1989, it was 4.5×10^9 km from the earth. Its radio transmitter, with which it sent back data and images, broadcast with a mere 21 W of power. Assuming that the transmitter broadcast equally in all directions,
  a. What signal intensity was received on the earth?
  b. What electric field amplitude was detected?

The received signal was somewhat stronger than your result because the spacecraft used a directional antenna, but not by much.

48. || In reading the instruction manual that came with your garage-door opener, you see that the transmitter unit in your car produces a 250 mW signal and that the receiver unit is supposed to respond to a radio wave of the correct frequency if the electric field amplitude exceeds 0.10 V/m. You wonder if this is really true. To find out, you put fresh batteries in the transmitter and start walking away from your garage while opening and closing the door. Your garage door finally fails to respond when you're 42 m away. Are the manufacturer's claims true?

49. || The maximum electric field strength in air is 3.0 MV/m. Stronger electric fields ionize the air and create a spark. What is the maximum power that can be delivered by a 1.0-cm-diameter laser beam propagating through air?

50. || The radar system at an airport broadcasts 11 GHz microwaves with 150 kW of power. An approaching airplane with a 31 m^2 cross section is 30 km away. Assume that the radar broadcasts uniformly in all directions and that the airplane scatters microwaves uniformly in all directions. What is the electric field strength of the microwave signal received back at the airport 200 μs later?

51. | The intensity of sunlight reaching the earth is 1360 W/m^2. Assuming all the sunlight is absorbed, what is the radiation-pressure force on the earth? Give your answer in newtons and as a fraction of the sun's gravitational force on the earth.

52. || A laser beam shines straight up onto a flat, black foil with a mass of 25 μg. What laser power is needed to levitate the foil?

53. | For a science project, you would like to horizontally suspend an 8.5 by 11 inch sheet of black paper in a vertical beam of light whose dimensions exactly match the paper. If the mass of the sheet is 1.0 g, what light intensity will you need?

54. || You've recently read about a chemical laser that generates a 20-cm-diameter, 25 MW laser beam. One day, after physics class, you start to wonder if you could use the radiation pressure from this laser beam to launch small payloads into orbit. To see if this might be feasible, you do a quick calculation of the acceleration of a 20-cm-diameter, 100 kg, perfectly absorbing block. What speed would such a block have if pushed *horizontally* 100 m along a frictionless track by such a laser?
55. || An 80 kg astronaut has gone outside his space capsule to do some repair work. Unfortunately, he forgot to lock his safety tether in place, and he has drifted 5.0 m away from the capsule. Fortunately, he has a 1000 W portable laser with fresh batteries that will operate it for 1.0 hr. His only chance is to accelerate himself toward the space capsule by firing the laser in the opposite direction. He has a 10-hr supply of oxygen. Can he make it?
56. || Unpolarized light of intensity I_0 is incident on three polarizing filters. The axis of the first is vertical, that of the second is 45° from vertical, and that of the third is horizontal. What light intensity emerges from the third filter?

Challenge Problems

57. An electron travels with $\vec{v} = 5.0 \times 10^6 \hat{\imath}$ m/s through a point in space where $\vec{B} = 0.10\hat{\jmath}$ T. The force on the electron at this point is $\vec{F} = (9.6 \times 10^{-14}\hat{\imath} - 9.6 \times 10^{-14}\hat{k})$ N. What is the electric field?
58. A 4.0-cm-diameter parallel-plate capacitor with a 1.0 mm spacing is charged to 1000 V. A switch closes at $t = 0$ s, and the capacitor is discharged through a wire with 0.20 Ω resistance.
    a. Find an expression for the magnetic field strength inside the capacitor at $r = 1.0$ cm as a function of time.
    b. Draw a graph of B versus t.
59. A 1.0 μF capacitor is discharged, starting at $t = 0$ s. The displacement current through the plates is $I_{disp} = (10\text{ A})\exp(-t/2.0\ \mu\text{s})$. What was the capacitor's initial voltage $(\Delta V_C)_0$?
60. Large quantities of dust should have been left behind after the creation of the solar system. Larger dust particles, comparable in size to soot and sand grains, are common. They create shooting stars when they collide with the earth's atmosphere. But very small dust particles are conspicuously absent. Astronomers believe that the very small dust particles have been blown out of the solar system by the sun. By comparing the forces on dust particles, determine the diameter of the smallest dust particles that can remain in the solar system over long periods of time. Assume that the dust particles are spherical, black, and have a density of 2000 kg/m^3. The sun emits electromagnetic radiation with power 3.9×10^{26} W.
61. Consider current I passing through a resistor of radius r, length L, and resistance R.
    a. Determine the electric and magnetic fields at the surface of the resistor. Assume that the electric field is uniform throughout, including at the surface.
    b. Determine the strength and direction of the Poynting vector at the surface of the resistor.
    c. Show that the flux of the Poynting vector (i.e., the integral of $\vec{S} \cdot d\vec{A}$) over the surface of the resistor is I^2R. Then give an interpretation of this result.
62. Unpolarized light of intensity I_0 is incident on a stack of 7 polarizing filters, each with its axis rotated 15° cw with respect to the previous filter. What light intensity emerges from the last filter?

STOP TO THINK ANSWERS

Stop to Think 35.1: b. $\vec{V}$ is parallel to $\vec{B}$, hence $\vec{V} \times \vec{B}$ is zero. Thus $\vec{E}' = \vec{E}$ and points in the positive z-direction. $\vec{V} \times \vec{E}$ points down, in the negative y direction, so $-\vec{V} \times \vec{E}/c^2$ points in the positive y-direction and causes $\vec{B}'$ to be angled upward.

Stop to Think 35.2: $B_c > B_a > B_d > B_b$. The induced magnetic field strength depends on the *rate* dE/dt at which the electric field is changing. Steeper slopes on the graph correspond to larger magnetic fields.

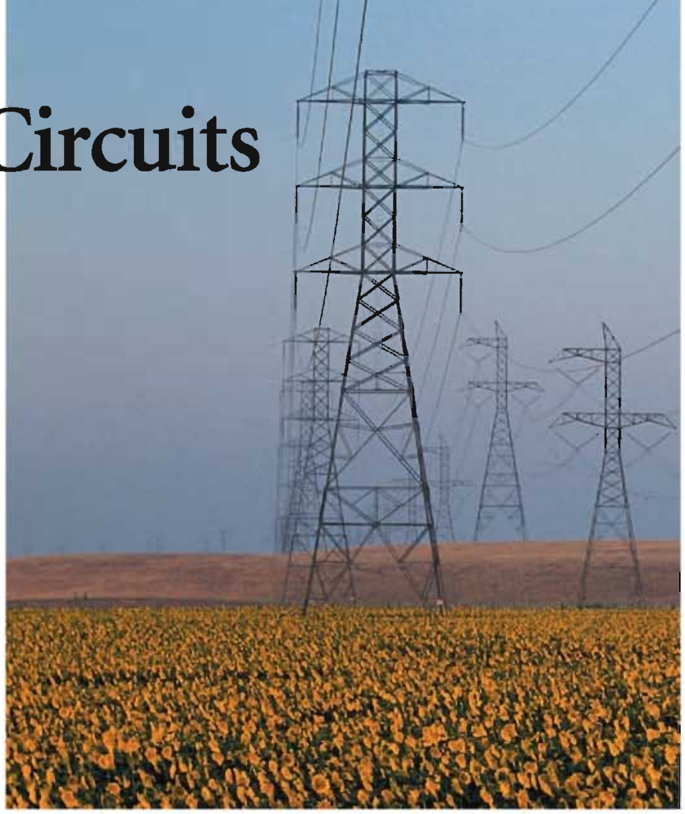
Stop to Think 35.3: e. $\vec{E}$ is perpendicular to $\vec{B}$ and to $\vec{v}$, so it can only be along the z-axis. According to the Ampère-Maxwell law, $d\Phi_e/dt$ has the same sign as the line integral of $\vec{B} \cdot d\vec{s}$ around the closed curve. The integral is positive for a cw integration. Thus, from the right-hand rule, $\vec{E}$ is either into the page (negative z-direction) and increasing, or out of the page (positive z-direction) and decreasing. We can see from the figure that B is decreasing as the wave moves from left to right, so E must also be decreasing. Thus $\vec{E}$ points along the positive z-axis.

Stop to Think 35.4: a. The Poynting vector $\vec{S} = (\vec{E} \times \vec{B})/\mu_0$ points in the direction of travel, which is the positive y-direction. $\vec{B}$ must point in the positive x-direction in order for $\vec{E} \times \vec{B}$ to point upward.

Stop to Think 35.5: b. The intensity along a line from the antenna decreases inversely with the square of the distance, so the intensity at 20 km is $\frac{1}{4}$ that at 10 km. But the intensity depends on the square of the electric field amplitude, or, conversely, E_0 is proportional to $I^{1/2}$. Thus E_0 at 20 km is $\frac{1}{2}$ that at 10 km.

Stop to Think 35.6: $I_d > I_a > I_b = I_c$. The intensity depends on $\cos^2\theta$, where θ is the angle *between* the axes of the two filters. The filters in d have $\theta = 0°$. The two filters in both b and c are crossed ($\theta = 90°$) and transmit no light at all.

36 AC Circuits



Transmission lines carry alternating current at voltages as high as 500,000 V.

▶ Looking Ahead
The goal of Chapter 36 is to understand and apply basic techniques of AC circuit analysis. In this chapter you will learn to:

- Use phasors to analyze an AC circuit with resistors, capacitors, and inductors.
- Understand *RC* filter circuits.
- Understand resonance in an *RLC* circuit.
- Calculate the power loss in an AC circuit.

◀ Looking Back
The material in this chapter depends on the fundamentals of circuits and on the properties of resistors, capacitors, and inductors. The mathematical representation of AC circuits is based on simple harmonic motion. Please review:

- Sections 14.1,14.2, and 14.8 Simple harmonic motion and resonance.
- Section 30.5 Capacitors.
- Sections 32.1–32.4 Fundamentals of circuit analysis.
- Sections 34.8–34.10 Inductors.

Thomas Edison built the first large-scale electric generating station in 1882, in New York City. His entrepreneurial motive was to sell lightbulbs, which he had invented a few years earlier. Edison's company, which later became General Electric, is still one of the largest manufacturers of electrical equipment.

Edison soon had competition from George Westinghouse, another name that probably looks familiar. Whereas Edison's system used *direct current* (DC), Westinghouse favored *alternating current* (AC). The technological debate between these two men and their companies lasted 20 years, but eventually alternating current proved to be superior for the long-distance transmission of electric energy.

Today, more than a century later, a "grid" of AC electrical distribution systems spans the United States and other countries. Any device that plugs into an electric outlet uses an AC circuit. In this chapter, you will learn some of the basic techniques for analyzing AC circuits. However, these ideas are not limited to power-line circuits. Audio, radio, television, and telecommunication electronics are based on circuits that use oscillating voltages and currents. Any practical understanding of modern electronics is grounded, so to speak, in AC circuit analysis.

36.1 AC Sources and Phasors

One of the examples of Faraday's law cited in Chapter 34 was an electric generator. A turbine, which might be powered by expanding steam or falling water, causes a coil of wire to rotate in a magnetic field. As the coil spins, the emf and the induced current

oscillate sinusoidally. The emf is alternately positive and negative, causing the charges to flow in one direction and then, a half cycle later, in the other. The oscillation frequency in North and South America is $f = 60$ Hz, whereas most of the rest of the world uses a 50 Hz oscillation.

The generator's emf—the voltage—is determined by the magnetic field strength and the number of turns in the generator coil. The emf is a fixed, unvarying quantity, so it might seem logical to call a generator an *alternating voltage source.* Nonetheless, circuits powered by a sinusoidal emf are called **AC circuits,** where AC stands for *alternating current.* By contrast, the steady-current circuits you studied in Chapter 32 are called **DC circuits,** for *direct current.*

AC circuits are not limited to the use of 50 Hz or 60 Hz power-line voltages. Audio, radio, television, and telecommunication equipment all make extensive use of AC circuits, with frequencies ranging from approximately 10^2 Hz in audio circuits to approximately 10^9 Hz in cell phones. These devices use *electrical oscillators* rather than generators to produce a sinusoidal emf, but the basic principles of circuit analysis are the same.

You can think of an AC generator or oscillator as a battery whose output voltage undergoes sinusoidal oscillations. The instantaneous emf of an AC generator or oscillator, shown graphically in FIGURE 36.1a, can be written

$$\mathcal{E} = \mathcal{E}_0 \cos \omega t \tag{36.1}$$

where $\mathcal{E}_0$ is the peak or maximum emf and $\omega = 2\pi f$ is the angular frequency in radians per second. Recall that the units of emf are volts. As you can imagine, the mathematics of AC circuit analysis are going to be very similar to the mathematics of simple harmonic motion.

An alternative way to represent the emf and other oscillatory quantities is with the *phasor diagram* of FIGURE 36.1b. A **phasor** is a vector that rotates *counterclockwise* (ccw) around the origin at angular frequency ω. The length or magnitude of the phasor is the maximum value of the quantity. For example, the length of an emf phasor is $\mathcal{E}_0$. The angle ωt is the *phase angle,* an idea you learned about in Chapter 14, where we made a connection between circular motion and simple harmonic motion.

The quantity's instantaneous value, the value you would measure at time t, is the projection of the phasor onto the horizontal axis. This is also analogous to the connection between circular motion and simple harmonic motion. FIGURE 36.2 helps you visualize the phasor rotation by showing how the phasor corresponds to the more familiar graph at several specific points in the cycle.

FIGURE 36.1 An oscillating emf can be represented as a graph or as a phasor diagram.

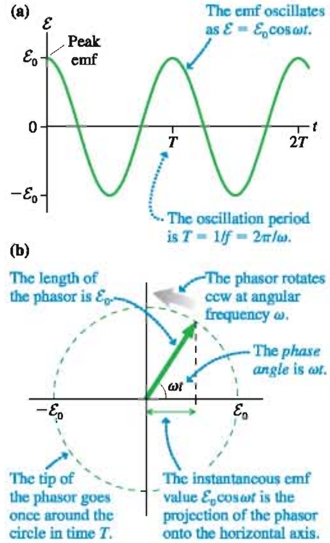


FIGURE 36.2 The correspondence between a phasor and points on a graph.

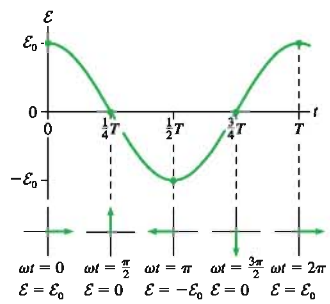
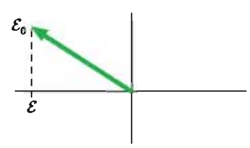


STOP TO THINK 36.1 The magnitude of the instantaneous value of the emf represented by this phasor is



a. Increasing.
b. Decreasing.
c. Constant.
d. It's not possible to tell without knowing t.

Resistor Circuits

In Chapter 32 you learned to analyze a circuit in terms of the current I, voltage V, and potential difference ΔV. Now, because the current and voltage are oscillating, we will use lowercase i to represent the *instantaneous* current through a circuit element and v for the circuit element's *instantaneous* voltage.

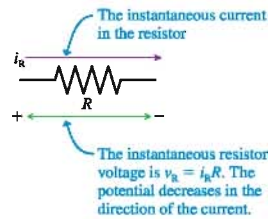


FIGURE 36.3 Instantaneous current i_R through a resistor.

FIGURE 36.3 shows the instantaneous current i_R through a resistor R. The potential difference across the resistor, which we call the *resistor voltage* v_R, is given by Ohm's law:

$$v_R = i_R R \tag{36.2}$$

The potential *decreases* in the direction of the current.

FIGURE 36.4 shows a resistor R connected across an AC emf $\mathcal{E}$. Notice that the circuit symbol for an AC generator is —~—. We can analyze this circuit in exactly the same way we analyzed a DC resistor circuit. Kirchhoff's loop law says that the sum of all the potential differences around a closed path is zero:

$$\sum \Delta V = \Delta V_{source} + \Delta V_R = \mathcal{E} - v_R = 0 \tag{36.3}$$

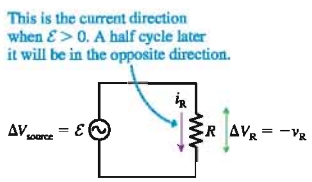

FIGURE 36.4 An AC resistor circuit.

The minus sign appears, just as it did in the equation for a DC circuit, because the potential *decreases* when we travel through a resistor in the direction of the current. We find from the loop law that $v_R = \mathcal{E} = \mathcal{E}_0 \cos\omega t$. This isn't surprising because the resistor is connected directly across the terminals of the emf.

The resistor voltage is a sinusoidal voltage at angular frequency ω. It will be useful to write

$$v_R = V_R \cos\omega t \tag{36.4}$$

where V_R is the peak or maximum voltage. You can see that $V_R = \mathcal{E}_0$ in the single-resistor circuit of Figure 36.4. Thus the current through the resistor is

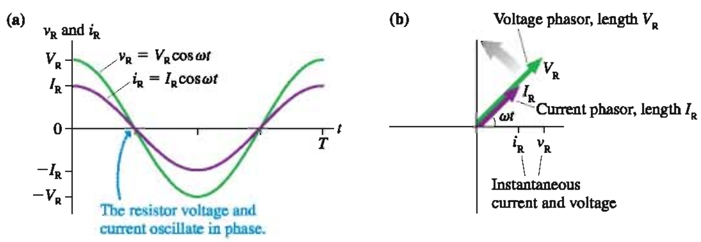
$$i_R = \frac{v_R}{R} = \frac{V_R \cos\omega t}{R} = I_R \cos\omega t \tag{36.5}$$

where $I_R = V_R/R$ is the peak current.

NOTE ► Ohm's law applies to both the instantaneous *and* peak currents and voltages. ◄

The resistor's instantaneous current and voltage are in phase, both oscillating as $\cos\omega t$. **FIGURE 36.5** shows the voltage and the current simultaneously on a graph and as a phasor diagram. The fact that the current phasor is shorter than the voltage phasor has no significance. Current and voltage are measured in different units, so you can't compare the length of one to the length of the other. Showing the two different quantities on a single graph—a tactic that can be misleading if you're not careful—illustrates that they oscillate in phase and that their phasors rotate together at the same angle and frequency.

FIGURE 36.5 Graph and phasor diagram of the resistor current and voltage. The current and voltage are in phase.



EXAMPLE 36.1 Finding resistor voltages

In the circuit of FIGURE 36.6, what are (a) the peak voltage across each resistor and (b) the instantaneous resistor voltages at $t = 20$ ms?

VISUALIZE Figure 36.6 shows the circuit diagram. The two resistors are in series.

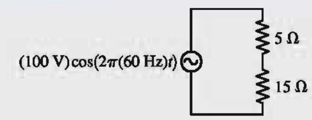
SOLVE a. The equivalent resistance of the two series resistors is $R_{eq} = 5\ \Omega + 15\ \Omega = 20\ \Omega$. The instantaneous current through the equivalent resistance is

$$i_R = \frac{v_R}{R_{eq}} = \frac{\mathcal{E}_0 \cos\omega t}{R_{eq}} = \frac{(100\ \text{V})\cos(2\pi(60\ \text{Hz})t)}{20\ \Omega}$$
$$= (5.0\ \text{A})\cos(2\pi(60\ \text{Hz})t)$$

The peak current is $I_R = 5.0$ A, and this is also the peak current through the two resistors that form the 20 Ω equivalent resistance. Hence the peak voltage across each resistor is

$$V_R = I_R R = \begin{cases} 25\ \text{V} & 5\ \Omega \text{ resistor} \\ 75\ \text{V} & 15\ \Omega \text{ resistor} \end{cases}$$

FIGURE 36.6 An AC resistor circuit.



b. The instantaneous current at $t = 0.020$ s is

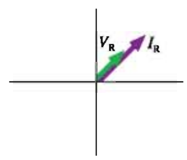
$$i_R = (5.0\ \text{A})\cos\big(2\pi(60\ \text{Hz})(0.020\ \text{s})\big) = 1.55\ \text{A}$$

The resistor voltages at this time are

$$v_R = i_R R = \begin{cases} 7.7\ \text{V} & 5\ \Omega \text{ resistor} \\ 23.2\ \text{V} & 15\ \Omega \text{ resistor} \end{cases}$$

ASSESS The sum of the instantaneous voltages, 30.9 V, is what you would find by calculating $\mathcal{E}$ at $t = 20$ ms. This self-consistency gives us confidence in the answer.

STOP TO THINK 36.2 The resistor whose voltage and current phasors are shown here has resistance R



a. >1 Ω
b. <1 Ω
c. It's not possible to tell.

36.2 Capacitor Circuits

FIGURE 36.7a shows current i_C charging a capacitor with capacitance C. The instantaneous capacitor voltage is $v_C = q/C$, where $\pm q$ is the charge on the two capacitor plates at this instant of time. It is useful to compare Figure 36.7a to Figure 36.3 for a resistor.

FIGURE 36.7b, where capacitance C is connected across an AC source of emf $\mathcal{E}$, is the most basic capacitor circuit. The capacitor is in parallel with the source, so the capacitor voltage equals the emf: $v_C = \mathcal{E} = \mathcal{E}_0 \cos\omega t$. It will be useful to write

$$v_C = V_C \cos\omega t \tag{36.6}$$

where V_C is the peak or maximum voltage across the capacitor. You can see that $V_C = \mathcal{E}_0$ in this single-capacitor circuit.

To find the current to and from the capacitor, we first write the charge

$$q = Cv_C = CV_C \cos\omega t \tag{36.7}$$

The current is the *rate* at which charge flows through the wires, $i_C = dq/dt$, thus

$$i_C = \frac{dq}{dt} = \frac{d}{dt}(CV_C \cos\omega t) = -\omega CV_C \sin\omega t \tag{36.8}$$

FIGURE 36.7 An AC capacitor circuit.

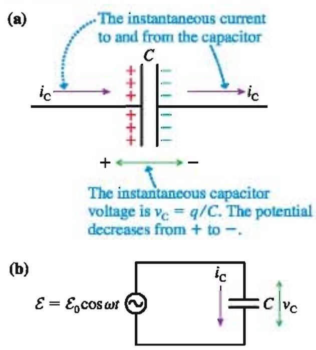


FIGURE 36.8 Graph and phasor diagrams of the capacitor current and voltage.

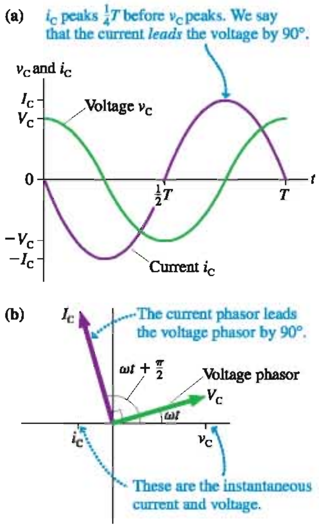


We can most easily see the relationship between the capacitor voltage and current if we use the trigonometric identity $-\sin(x) = \cos(x + \pi/2)$ to write

$$i_C = \omega C V_C \cos\left(\omega t + \frac{\pi}{2}\right) \tag{36.9}$$

In contrast to a resistor, a capacitor's current and voltage are *not* in phase. In FIGURE 36.8a, a graph of the instantaneous voltage v_C and current i_C, you can see that the current peaks one-quarter of a period *before* the voltage peaks. The phase angle of the current phasor on the phasor diagram of FIGURE 36.8b is $\pi/2$ rad—a quarter of a circle—larger than the phase angle of the voltage phasor.

We can summarize this finding:

The AC current to and from a capacitor *leads* the capacitor voltage by $\pi/2$ rad, or 90°.

The current reaches its peak value I_C at the instant the capacitor is fully discharged and $v_C = 0$. The current is zero at the instant the capacitor is fully charged. You saw a similar behavior in the oscillation of an LC circuit in Chapter 34.

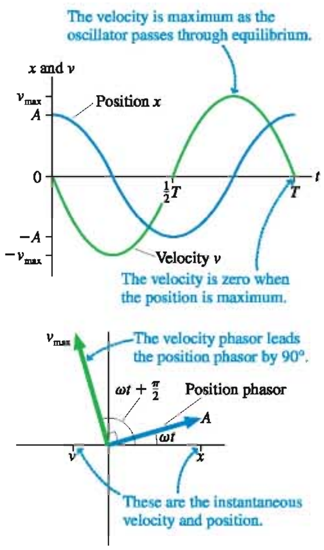
A simple harmonic oscillator provides a mechanical analogy of the 90° phase difference between current and voltage. You learned in Chapter 14 (refer to Section 14.1 and Figure 14.5) that the position and velocity of a simple harmonic oscillator are

$$x = A\cos\omega t$$

$$v = \frac{dx}{dt} = -\omega A \sin\omega t = -v_{max}\sin\omega t = v_{max}\cos\left(\omega t + \frac{\pi}{2}\right)$$

You can see in FIGURE 36.9 that the velocity leads the position by 90° in the same way that the capacitor current (which is proportional to the charge velocity) leads the voltage.

FIGURE 36.9 In a mechanical analogy, the velocity of a simple harmonic oscillator leads the position by 90°.



Capacitive Reactance

We can use Equation 36.9 to see that the peak current to and from a capacitor is $I_C = \omega C V_C$. This relationship between the peak voltage and peak current looks much like Ohm's law for a resistor if we define the **capacitive reactance** X_C to be

$$X_C \equiv \frac{1}{\omega C} \tag{36.10}$$

With this definition,

$$I_C = \frac{V_C}{X_C} \quad \text{or} \quad V_C = I_C X_C \tag{36.11}$$

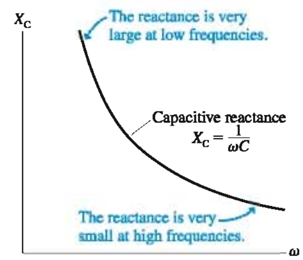
The units of reactance, like those of resistance, are ohms.

NOTE ▶ Reactance relates the *peak* voltage V_C and current I_C. But reactance differs from resistance in that it does *not* relate the instantaneous capacitor voltage and current because they are out of phase. That is, $v_C \neq i_C X_C$. ◀

A resistor's resistance R is independent of the emf frequency. In contrast, as FIGURE 36.10 shows, a capacitor's reactance X_C depends inversely on the frequency. The reactance becomes very large at low frequencies (i.e., the capacitor is a large impediment to current). This makes sense because $\omega = 0$ would be a nonoscillating DC cir-

cuit, and we know that a steady DC current cannot pass through a capacitor. The reactance decreases as the frequency increases until, at very high frequencies, $X_C \approx 0$ and the capacitor begins to act like an ideal wire. This result has important consequences for how capacitors are used in many circuits.

FIGURE 36.10 The capacitive reactance as a function of frequency.



EXAMPLE 36.2 Capacitive reactance

What is the capacitive reactance of a 0.10 μF capacitor at a 100 Hz audio frequency and at a 100 MHz FM-radio frequency?

SOLVE At 100 Hz,

$$X_C(\text{at } 100\text{ Hz}) = \frac{1}{\omega C} = \frac{1}{2\pi(100\text{ Hz})(1.0 \times 10^{-7}\text{ F})} = 16{,}000\ \Omega$$

Increasing the frequency by a factor of 10^6 decreases X_C by a factor of 10^6, giving

$$X_C(\text{at } 100\text{ MHz}) = 0.016\ \Omega$$

ASSESS A capacitor with a substantial reactance at audio frequencies has virtually no reactance at FM-radio frequencies.

EXAMPLE 36.3 Capacitor current

A 10 μF capacitor is connected to a 1000 Hz oscillator with a peak emf of 5.0 V. What is the peak current to the capacitor?

VISUALIZE Figure 36.7b showed the circuit diagram. It is a simple one-capacitor circuit.

SOLVE The capacitive reactance at $\omega = 2\pi f = 6280$ rad/s is

$$X_C = \frac{1}{\omega C} = \frac{1}{(6280\text{ rad/s})(10 \times 10^{-6}\text{ F})} = 16\ \Omega$$

The peak voltage across the capacitor is $V_C = \mathcal{E}_0 = 5.0$ V; hence the peak current is

$$I_C = \frac{V_C}{X_C} = \frac{5.0\text{ V}}{16\ \Omega} = 0.31\text{ A}$$

ASSESS Using reactance is just like using Ohm's law, but don't forget it applies to only the *peak* current and voltage, not the instantaneous values.

STOP TO THINK 36.3 What is the capacitive reactance of "no capacitor," just a continuous wire?

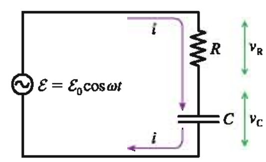
a. 0 b. ∞ c. Undefined

36.3 *RC* Filter Circuits

You learned in Chapter 32 that a resistance R causes a capacitor to be charged or discharged with time constant $\tau = RC$. We called this an *RC* circuit. Now that we've looked at resistors and capacitors individually, let's explore what happens if an *RC* circuit is driven continuously by an alternating current source.

FIGURE 36.11 shows a circuit in which a resistor R and capacitor C are in series with an emf $\mathcal{E}$ oscillating at angular frequency ω. Before launching into a formal analysis, let's try to understand qualitatively how this circuit will respond as the frequency is varied. If the frequency is very low, the capacitive reactance will be very large, and

FIGURE 36.11 An *RC* circuit driven by an AC source.



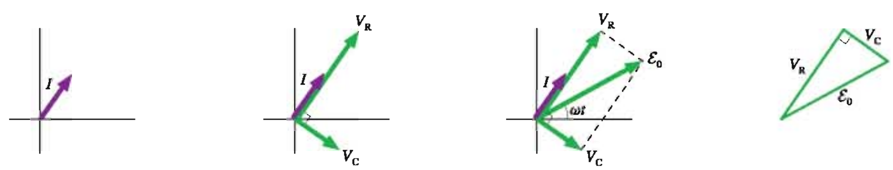
thus the peak current I_C will be very small. The peak current through the resistor is the same as the peak current to and from the capacitor (conservation of current requires $I_R = I_C$); hence we expect the resistor's peak voltage $V_R = I_R R$ to be very small at very low frequencies.

On the other hand, suppose the frequency is very high. Then the capacitive reactance approaches zero and the peak current, determined by the resistance alone, will be $I_R = \mathcal{E}_0/R$. The resistor's peak voltage $V_R = IR$ will approach the peak source voltage $\mathcal{E}_0$ at very high frequencies.

This reasoning leads us to expect that V_R will *increase* steadily from 0 to $\mathcal{E}_0$ as ω is increased from 0 to very high frequencies. Kirchhoff's loop law has to be obeyed, so the capacitor voltage V_C will *decrease* from $\mathcal{E}_0$ to 0 during the same change of frequency. A quantitative analysis will show us how this behavior can be used as a *filter.*

The goal of a quantitative analysis is to determine the peak current I and the two peak voltages V_R and V_C as functions of the emf amplitude $\mathcal{E}_0$ and frequency ω. Although this goal can be reached with a purely algebraic analysis, using a phasor diagram is easier and more informative. Our analytic procedure is based on the fact that the instantaneous current i is the same for two circuit elements in series.

Analyzing an *RC* circuit



Begin by drawing a current phasor of length I. This is the starting point because the series circuit elements have the same current i. The angle at which the phasor is drawn is not relevant.

The current and voltage of a resistor are in phase, so draw a resistor voltage phasor of length V_R parallel to the current phasor I. The capacitor current leads the capacitor voltage by 90°, so draw a capacitor voltage phasor of length V_C that is 90° behind [i.e., clockwise (cw) from] the current phasor.

The series resistor and capacitor are in parallel with the emf, so their *instantaneous* voltages satisfy $v_R + v_C = \mathcal{E}$. This is a *vector* addition of phasors, so draw the emf phasor as the vector sum of the two voltage phasors. The emf is $\mathcal{E} = \mathcal{E}_0 \cos\omega t$, hence the emf phasor is at angle ωt.

The length of the emf phasor, $\mathcal{E}_0$, is the hypotenuse of a right triangle formed by the resistor and capacitor phasors. Thus $\mathcal{E}_0^2 = V_R^2 + V_C^2$.

The relationship $\mathcal{E}_0^2 = V_R^2 + V_C^2$ is based on the peak values, not the instantaneous values, because the peak values are the lengths of the sides of the right triangle. The peak voltages are related to the peak current I via $V_R = IR$ and $V_C = IX_C$, thus

$$\begin{aligned}\mathcal{E}_0^2 &= V_R^2 + V_C^2 = (IR)^2 + (IX_C)^2 = (R^2 + X_C^2)I^2 \\ &= (R^2 + 1/\omega^2 C^2)I^2\end{aligned} \tag{36.12}$$

Consequently, the peak current in the *RC* circuit is

$$I = \frac{\mathcal{E}_0}{\sqrt{R^2 + X_C^2}} = \frac{\mathcal{E}_0}{\sqrt{R^2 + 1/\omega^2 C^2}} \tag{36.13}$$

Knowing I gives us the two peak voltages:

$$\begin{aligned}V_R &= IR = \frac{\mathcal{E}_0 R}{\sqrt{R^2 + X_C^2}} = \frac{\mathcal{E}_0 R}{\sqrt{R^2 + 1/\omega^2 C^2}} \\ V_C &= IX_C = \frac{\mathcal{E}_0 X_C}{\sqrt{R^2 + X_C^2}} = \frac{\mathcal{E}_0/\omega C}{\sqrt{R^2 + 1/\omega^2 C^2}}\end{aligned} \tag{36.14}$$

Frequency Dependence

Our goal was to see how the peak current and voltages vary as functions of the frequency ω. Equations 36.13 and 36.14 are rather complex and best interpreted by looking at graphs. FIGURE 36.12 is a graph of V_R and V_C versus ω.

You can see that our qualitative predictions have been borne out. That is, V_R increases from 0 to $\mathcal{E}_0$ as ω is increased, while V_C decreases from $\mathcal{E}_0$ to 0. The explanation for this behavior is that the capacitive reactance X_C decreases as ω increases. For low frequencies, where $X_C \gg R$, the circuit is primarily capacitive. For high frequencies, where $X_C \ll R$, the circuit is primarily resistive.

The frequency at which $V_R = V_C$ is called the **crossover frequency** ω_c. The *crossover* frequency is easily found by setting the two expressions in Equation 36.14 equal to each other. The denominators are the same and cancel, as does $\mathcal{E}_0$, leading to

$$\omega_c = \frac{1}{RC} \qquad (36.15)$$

In practice, $f_c = \omega_c/2\pi$ is also called the crossover frequency.

We'll leave it as a homework problem to show that $V_R = V_C = \mathcal{E}_0/\sqrt{2}$ when $\omega = \omega_c$. This may seem surprising. After all, shouldn't V_R and V_C add up to $\mathcal{E}_0$?

No! V_R and V_C are the *peak values* of oscillating voltages, not the instantaneous values. The instantaneous values do, indeed, satisfy $v_R + v_C = \mathcal{E}$ at all instants of time. But the resistor and capacitor voltages are out of phase with each other, as the phasor diagram shows, so the two circuit elements don't reach their peak values at the same time. The peak values are related by $\mathcal{E}_0^2 = V_R^2 + V_C^2$, and you can see that $V_R = V_C = \mathcal{E}_0/\sqrt{2}$ satisfies this equation.

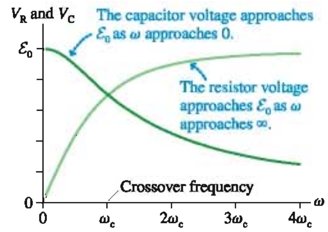


FIGURE 36.12 Graph of the resistor and capacitor peak voltages as functions of the emf angular frequency ω.

NOTE ▶ It's very important in AC circuit analysis to make a clear distinction between instantaneous values and peak values of voltages and currents. Relationships that are true for one set of values may not be true for the other. ◀

Filters

FIGURE 36.13a is the circuit we've just analyzed; the only difference is that the capacitor voltage v_C is now identified as the *output voltage* v_{out}. This is a voltage you might measure or, perhaps, send to an amplifier for use elsewhere in an electronic instrument. You can see from the capacitor voltage graph in Figure 36.12 that the peak output voltage is $V_{out} \approx \mathcal{E}_0$ if $\omega \ll \omega_c$, but $V_{out} \approx 0$ if $\omega \gg \omega_c$. In other words,

- If the frequency of an input signal is well below the crossover frequency, the input signal is transmitted with little loss to the output.
- If the frequency of an input signal is well above the crossover frequency, the input signal is strongly attenuated and the output is very nearly zero.

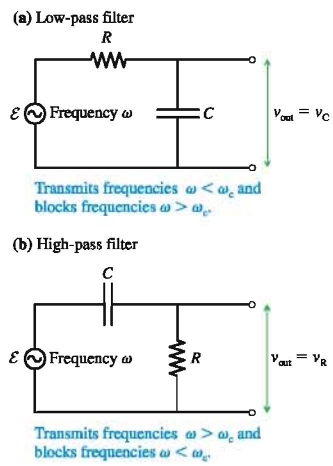
This circuit is called a **low-pass filter.**

The circuit of FIGURE 36.13b, which instead uses the resistor voltage v_R for the output v_{out}, is a **high-pass filter.** The output is $V_{out} \approx 0$ if $\omega \ll \omega_c$, but $V_{out} \approx \mathcal{E}_0$ if $\omega \gg \omega_c$. That is, an input signal whose frequency is well above the crossover frequency is transmitted without loss to the output.

Filter circuits are widely used in electronics. For example, a high-pass filter designed to have $f_c = 100$ Hz would pass the audio frequencies associated with speech ($f > 200$ Hz) while blocking 60 Hz "noise" that can be picked up from power lines. Similarly, the high-frequency hiss from old vinyl records can be attenuated with a low-pass filter, allowing the lower-frequency audio signal to pass.

A simple *RC* filter suffers from the fact that the crossover region where $V_R \approx V_C$ is fairly broad. More sophisticated filters have a sharper transition from off ($V_{out} \approx 0$) to on ($V_{out} \approx \mathcal{E}_0$), but they're based on the same principles as the *RC* filter analyzed here.

FIGURE 36.13 Low-pass and high-pass filter circuits.



EXAMPLE 36.4 Designing a filter

For a science project, you've built a radio to listen to AM radio broadcasts at frequencies near 1 MHz. The basic circuit is an antenna, which produces a very small oscillating voltage when it absorbs the energy of an electromagnetic wave, and an amplifier. Unfortunately, your neighbor's short-wave radio broadcast at 10 MHz interferes with your reception. Having just finished physics, you decide to solve this problem by placing a filter between the antenna and the amplifier. You happen to have a 500 pF capacitor. What frequency should you select as the filter's crossover frequency? What value of resistance will you need to build this filter?

MODEL You need a low-pass filter to block signals at 10 MHz while passing the lower-frequency AM signal at 1 MHz.

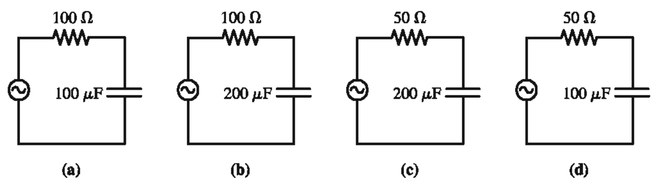
VISUALIZE The circuit will look like the low-pass filter in Figure 36.13a. The oscillating voltage generated by the antenna will be the emf, and v_{out} will be sent to the amplifier.

SOLVE You might think that a crossover frequency near 5 MHz, about halfway between 1 MHz and 10 MHz, would work best. But 5 MHz is a factor of 5 higher than 1 MHz while only a factor of 2 less than 10 MHz. A crossover frequency the same factor above 1 MHz as it is below 10 MHz will give the best results. In practice, choosing $f_c = 3$ MHz would be sufficient. You can then use Equation 36.15 to select the proper resistor value:

$$R = \frac{1}{\omega_c C} = \frac{1}{2\pi(3 \times 10^6\ \text{Hz})(500 \times 10^{-12}\ \text{F})}$$
$$= 106\ \Omega \approx 100\ \Omega$$

ASSESS Rounding to 100 Ω is appropriate because the crossover frequency was determined to only one significant figure. Such "sloppy design" is adequate when the two frequencies you need to distinguish are well separated.

STOP TO THINK 36.4 Rank in order, from largest to smallest, the crossover frequencies $(\omega_c)_a$ to $(\omega_c)_d$ of these four circuits.



36.4 Inductor Circuits

FIGURE 36.14 Using an inductor in an AC circuit.

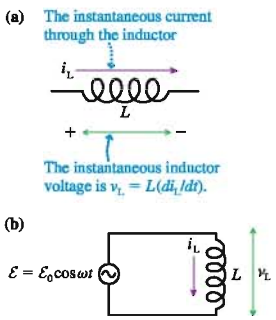


FIGURE 36.14a shows the instantaneous current i_L through an inductor. If the current is changing, the instantaneous inductor voltage is

$$v_L = L\frac{di_L}{dt} \tag{36.16}$$

You learned in Chapter 34 that the potential decreases in the direction of the current if the current is increasing $(di_L/dt > 0)$ and increases if the current is decreasing $(di_L/dt < 0)$.

FIGURE 36.14b is the simplest inductor circuit. The inductor L is connected across the AC source, so the inductor voltage equals the emf: $v_L = \mathcal{E} = \mathcal{E}_0 \cos\omega t$. We can write

$$v_L = V_L \cos\omega t \tag{36.17}$$

where V_L is the peak or maximum voltage across the inductor. You can see that $V_L = \mathcal{E}_0$ in this single-inductor circuit.

We can find the inductor current i_L by integrating Equation 36.17. First, use Equation 36.17 to write Equation 36.16 as

$$di_L = \frac{v_L}{L}dt = \frac{V_L}{L}\cos\omega t\, dt \tag{36.18}$$

Integrating gives

$$i_L = \frac{V_L}{L}\int \cos\omega t\,dt = \frac{V_L}{\omega L}\sin\omega t = \frac{V_L}{\omega L}\cos\left(\omega t - \frac{\pi}{2}\right)$$
$$= I_L\cos\left(\omega t - \frac{\pi}{2}\right) \qquad (36.19)$$

where $I_L = V_L/\omega L$ is the peak or maximum inductor current.

NOTE ▶ Mathematically, Equation 36.19 could have an integration constant i_0. An integration constant would represent a constant DC current through the inductor, but there is no DC source of potential in an AC circuit. Hence, on physical grounds, we set $i_0 = 0$ for an AC circuit. ◀

We define the **inductive reactance,** analogous to the capacitive reactance, to be

$$X_L \equiv \omega L \qquad (36.20)$$

Then the peak current $I_L = V_L/\omega L$ and the peak voltage are related by

$$I_L = \frac{V_L}{X_L} \quad \text{or} \quad V_L = I_L X_L \qquad (36.21)$$

FIGURE 36.15 shows that the inductive reactance increases as the frequency increases. This makes sense. Faraday's law tells us that the induced voltage across a coil increases as the time rate of change of $\vec{B}$ increases, and $\vec{B}$ is directly proportional to the inductor current. For a given peak current I_L, $\vec{B}$ changes more rapidly at higher frequencies than at lower frequencies, and thus V_L is larger at higher frequencies than at lower frequencies.

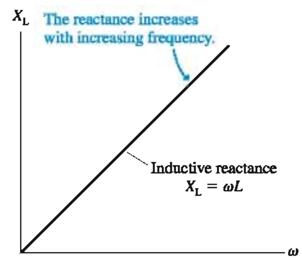

FIGURE 36.15 The inductive reactance as a function of frequency.

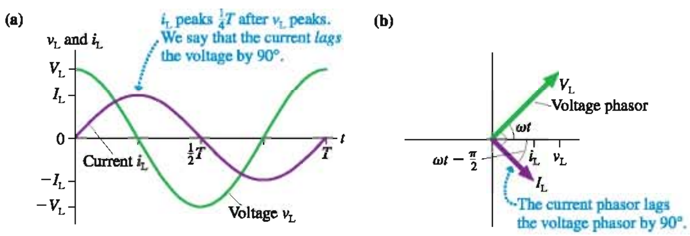
FIGURE 36.16a is a graph of the inductor voltage and current. You can see that the current peaks one-quarter of a period *after* the voltage peaks. The angle of the current phasor on the phasor diagram of **FIGURE 36.16b** is $\pi/2$ rad less than the angle of the voltage phasor. We can summarize this finding:

The AC current through an inductor *lags* the inductor voltage by $\pi/2$ rad, or 90°.

FIGURE 36.16 Graphs and phasor diagrams of the inductor current and voltage.



EXAMPLE 36.5 Current and voltage of an inductor

A 25 μH inductor is used in a circuit that oscillates at 100 kHz. The current through the inductor reaches a peak value of 20 mA at $t = 5.0\ \mu$s. What is the peak inductor voltage, and when, closest to $t = 5.0\ \mu$s, does it occur?

MODEL The inductor current lags the voltage by 90°, or, equivalently, the voltage reaches its peak value one-quarter period *before* the current.

VISUALIZE The circuit looks like Figure 36.14b.

SOLVE The inductive reactance at $f = 100$ kHz is

$$X_L = \omega L = 2\pi(1.0 \times 10^5\ \text{Hz})(25 \times 10^{-6}\ \text{H}) = 16\ \Omega$$

Thus the peak voltage is $V_L = I_L X_L = (20\ \text{mA})(16\ \Omega) = 320$ mV. The voltage peak occurs one-quarter period before the current peaks, and we know that the current peaks at $t = 5.0\ \mu$s. The period of a 100 kHz oscillation is 10.0 μs, so the voltage peaks at

$$t = 5.0\ \mu\text{s} - \frac{10.0\ \mu\text{s}}{4} = 2.5\ \mu\text{s}$$

36.5 The Series *RLC* Circuit

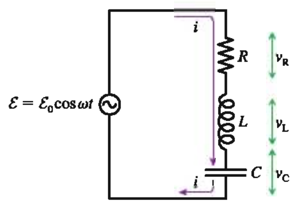


FIGURE 36.17 A series *RLC* circuit.

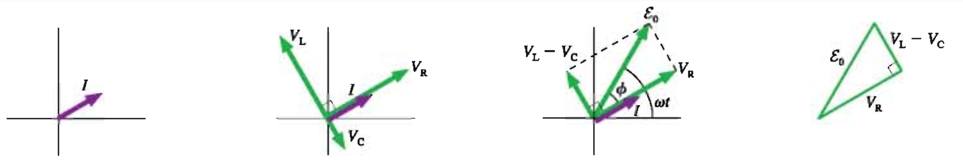
The circuit of **FIGURE 36.17**, where a resistor, inductor, and capacitor are in series, is called a **series *RLC* circuit.** The series *RLC* circuit has many important applications because, as you will see, it exhibits resonance behavior.

The analysis, which is very similar to our analysis of the *RC* circuit in Section 36.3, will be based on a phasor diagram. Notice that the three circuit elements are in series with each other and, together, are in parallel with the emf. We can draw two conclusions that form the basis of our analysis:

1. The instantaneous current of all three elements is the same: $i = i_R = i_L = i_C$.
2. The sum of the instantaneous voltages matches the emf: $\mathcal{E} = v_R + v_L + v_C$.

Analyzing an *RLC* circuit



Begin by drawing a current phasor of length I. This is the starting point because the series circuit elements have the same current i.

The current and voltage of a resistor are in phase, so draw a resistor voltage phasor parallel to the current phasor I. The capacitor current leads the capacitor voltage by 90°, so draw a capacitor voltage phasor that is 90° behind the current phasor. The inductor current *lags* the voltage by 90°, so draw an inductor voltage phasor 90° ahead of the current phasor.

The instantaneous voltages satisfy $\mathcal{E} = v_R + v_L + v_C$. In terms of phasors, this is a *vector* addition. We can do the addition in two steps. Because the capacitor and inductor phasors are in opposite directions, their vector sum has length $V_L - V_C$. Adding the resistor phasor, at right angles, then gives the emf phasor $\mathcal{E}$ at angle ωt.

The length $\mathcal{E}_0$ of the emf phasor is the hypotenuse of a right triangle. Thus

$$\mathcal{E}_0^2 = V_R^2 + (V_L - V_C)^2$$

14.2, 14.3 ActivPhysics ONLINE

If $V_L > V_C$, which we've assumed, then the instantaneous current i lags the emf by a phase angle ϕ. We can write the current, in terms of ϕ, as

$$i = I\cos(\omega t - \phi) \qquad (36.22)$$

Of course, there's no guarantee that V_L will be larger than V_C. If the opposite is true, $V_L < V_C$, the emf phasor is on the other side of the current phasor. Our analysis is still valid if we consider ϕ to be negative when i is ccw from $\mathcal{E}$. Thus ϕ can be anywhere between $-90°$ and $+90°$.

Now we can continue much as we did with the *RC* circuit. Based on the right triangle, $\mathcal{E}_0^2$ is

$$\mathcal{E}_0^2 = V_R^2 + (V_L - V_C)^2 = [R^2 + (X_L - X_C)^2]I^2 \qquad (36.23)$$

where we wrote each of the peak voltages in terms of the peak current I and a resistance or a reactance. Consequently, the peak current in the *RLC* circuit is

$$I = \frac{\mathcal{E}_0}{\sqrt{R^2 + (X_L - X_C)^2}} = \frac{\mathcal{E}_0}{\sqrt{R^2 + (\omega L - 1/\omega C)^2}} \qquad (36.24)$$

The three peak voltages, if you need them, are then found from $V_R = IR$, $V_L = IX_L$, and $V_C = IX_C$.

Impedance

The denominator of Equation 36.24 is called the **impedance** Z of the circuit:

$$Z = \sqrt{R^2 + (X_L - X_C)^2} \tag{36.25}$$

Impedance, like resistance and reactance, is measured in ohms. The circuit's peak current can be written in terms of the source emf and the circuit impedance as

$$I = \frac{\mathcal{E}_0}{Z} \tag{36.26}$$

Equation 36.26 is a compact way to write I, but it doesn't add anything new to Equation 36.24.

Phase Angle

It is often useful to know the phase angle ϕ between the emf and the current. You can see from FIGURE 36.18 that

$$\tan\phi = \frac{V_L - V_C}{V_R} = \frac{(X_L - X_C)I}{RI}$$

The current I cancels, and we're left with

$$\phi = \tan^{-1}\left(\frac{X_L - X_C}{R}\right) \tag{36.27}$$

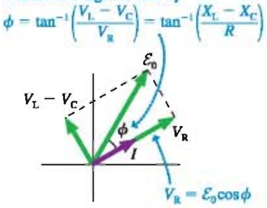


FIGURE 36.18 The current is not in phase with the emf.

We can check that Equation 36.27 agrees with our analyses of single-element circuits. A resistor-only circuit has $X_L = X_C = 0$ and thus $\phi = \tan^{-1}(0) = 0$ rad. In other words, as we discovered previously, the emf and current are in phase. An AC inductor circuit has $R = X_C = 0$ and thus $\phi = \tan^{-1}(\infty) = \pi/2$ rad, agreeing with our earlier finding that the inductor current lags the voltage by 90°. A homework problem will let you check that Equation 36.27 gives the correct result for an AC capacitor circuit.

Other relationships can be found from the phasor diagram and written in terms of the phase angle. For example, it is frequently useful to write the peak resistor voltage as

$$V_R = \mathcal{E}_0\cos\phi \tag{36.28}$$

Notice that the resistor voltage oscillates in phase with the emf only if $\phi = 0$ rad.

Resonance

Suppose we vary the emf frequency ω while keeping everything else constant. There is very little current at very low frequencies because the capacitive reactance $X_C = 1/\omega C$ is very large. Similarly, there is very little current at very high frequencies because the inductive reactance $X_L = \omega L$ becomes very large.

If I approaches zero at very low and very high frequencies, there should be some intermediate frequency where I is a maximum. Indeed, you can see from Equation 36.24 that the denominator will be a minimum, making I a maximum, when $X_L = X_C$, or

$$\omega L = \frac{1}{\omega C} \tag{36.29}$$

The frequency ω_0 that satisfies Equation 36.39 is called the **resonance frequency:**

$$\omega_0 = \frac{1}{\sqrt{LC}} \tag{36.30}$$

This is the frequency for *maximum current* in the series *RLC* circuit. The maximum current

$$I_{max} = \frac{\mathcal{E}_0}{R} \tag{36.31}$$

is that of a purely resistive circuit because the impedance is $Z = R$ at resonance.

You'll recognize ω_0 as the oscillation frequency of the *LC* circuit we analyzed in Chapter 34. The current in an ideal *LC* circuit oscillates forever as energy is transferred back and forth between the capacitor and the inductor. This is analogous to an ideal, frictionless simple harmonic oscillator in which the energy is transformed back and forth between kinetic and potential.

Adding a resistor to the circuit is like adding damping to a mechanical oscillator. The emf is then a sinusoidal driving force, and the series *RLC* circuit is directly analogous to the driven, damped oscillator that you studied in Chapter 14. A mechanical oscillator exhibits *resonance* by having a large-amplitude response when the driving frequency matches the system's natural frequency. Equation 36.30 is the natural frequency of the series *RLC* circuit, the frequency at which the current would like to oscillate. Consequently, the circuit has a large current response when the oscillating emf matches this frequency.

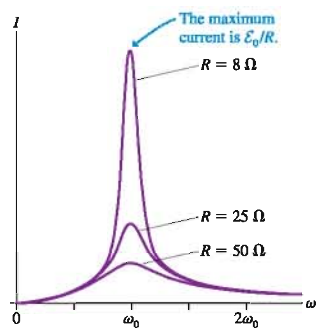

FIGURE 36.19 A graph of the current I versus emf frequency for a series *RLC* circuit.

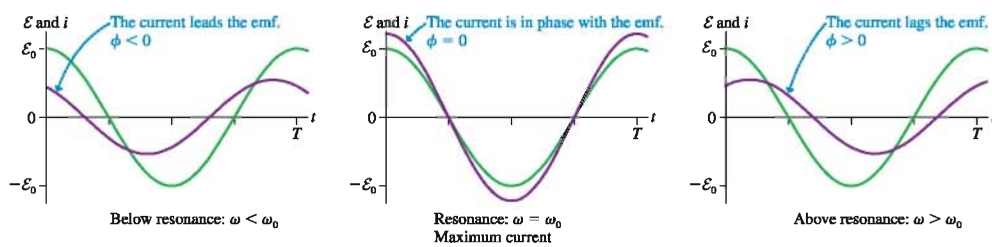
FIGURE 36.19 shows the peak current I of a series *RLC* circuit as the emf frequency ω is varied. Notice how the current increases until reaching a maximum at frequency ω_0, then decreases. This is the hallmark of a resonance.

As R decreases, causing the damping to decrease, the maximum current becomes larger and the curve in Figure 36.19 becomes narrower. You saw exactly the same behavior for a driven mechanical oscillator. The emf frequency must be very close to ω_0 in order for a lightly damped system to respond, but the response at resonance is very large.

For a different perspective, FIGURE 36.20 graphs the instantaneous emf $\mathcal{E} = \mathcal{E}_0 \cos\omega t$ and current $i = I\cos(\omega t - \phi)$ for frequencies below, at, and above ω_0. The current and the emf are in phase at resonance ($\phi = 0$ rad) because the capacitor and inductor essentially cancel each other to give a purely resistive circuit. Away from resonance, the current decreases *and* begins to get out of phase with the emf. You can see, from Equation 36.27, that the phase angle ϕ is negative when $X_L < X_C$ (i.e., the frequency is below resonance) and positive when $X_L > X_C$ (the frequency is above resonance).

Resonance circuits are widely used in radio, television, and communication equipment because of their ability to respond to one particular frequency (or very narrow range of frequencies) while suppressing others. The selectivity of a resonance circuit improves as the resistance decreases, but the inherent resistance of the wires and the inductor coil keeps R from being $0\ \Omega$.

FIGURE 36.20 Graphs of the emf $\mathcal{E}$ and the current I at frequencies below, at, and above the resonance frequency ω_0.



EXAMPLE 36.6 Designing a radio receiver

An AM radio antenna picks up a 1000 kHz signal with a peak voltage of 5.0 mV. The tuning circuit consists of a 60 μH inductor in series with a variable capacitor. The inductor coil has a resistance of 0.25 Ω, and the resistance of the rest of the circuit is negligible.

a. To what value should the capacitor be tuned to listen to this radio station?
b. What is the peak current through the circuit at resonance?
c. A stronger station at 1050 kHz produces a 10 mV antenna signal. What is the current at this frequency when the radio is tuned to 1000 kHz?

MODEL The inductor's 0.25 Ω resistance can be modeled as a resistance in series with the inductance, hence we have a series *RLC* circuit. The antenna signal at $\omega = 2\pi \times 1000$ kHz is the emf.

VISUALIZE The circuit looks like Figure 36.17.

SOLVE a. The capacitor needs to be tuned to where it and the inductor are resonant at $\omega_0 = 2\pi \times 1000$ kHz. The appropriate value is

$$C = \frac{1}{L\omega_0^2} = \frac{1}{(60 \times 10^{-6}\,\text{H})(6.28 \times 10^6\,\text{rad/s})^2}$$
$$= 4.2 \times 10^{-10}\,\text{F} = 420\,\text{pF}$$

b. $X_L = X_C$ at resonance, so the peak current is

$$I = \frac{\mathcal{E}_0}{R} = \frac{5.0 \times 10^{-3}\,\text{V}}{0.25\,\Omega} = 0.020\,\text{A} = 20\,\text{mA}$$

c. The 1050 kHz signal is "off resonance," so we need to compute $X_L = \omega L = 396\,\Omega$ and $X_C = 1/\omega C = 358\,\Omega$ at $\omega = 2\pi \times 1050$ kHz. The peak voltage of this signal is $\mathcal{E}_0 = 10$ mV. With these values, Equation 36.24 for the peak current is

$$I = \frac{\mathcal{E}_0}{\sqrt{R^2 + (X_L - X_C)^2}} = 0.26\,\text{mA}$$

ASSESS These are realistic values for the input stage of an AM radio. You can see that the signal from the 1050 kHz station is strongly suppressed when the radio is tuned to 1000 kHz.

STOP TO THINK 36.5 A series *RLC* circuit has $V_C = 5.0$ V, $V_R = 7.0$ V, and $V_L = 9.0$ V. Is the frequency above, below, or equal to the resonance frequency?

36.6 Power in AC Circuits

A primary role of the emf is to supply energy. Some circuit devices, such as motors and lightbulbs, use the energy to perform useful tasks. Other circuit devices dissipate the energy as an increased thermal energy in the components and the surrounding air. Chapter 32 examined the topic of power in DC circuits. Now we can perform a similar analysis for AC circuits.

The emf supplies energy to a circuit at the rate

$$p_{\text{source}} = i\mathcal{E} \tag{36.32}$$

where i and $\mathcal{E}$ are the instantaneous current from and potential difference across the emf. We've used a lowercase p to indicate that this is the instantaneous power. We need to look at the power losses in individual circuit elements.

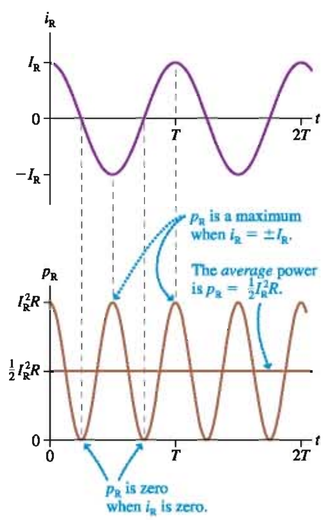


FIGURE 36.21 The instantaneous power loss in a resistor.

Resistors

You learned in Chapter 32 that the current through a resistor causes the resistor to dissipate energy at the rate

$$p_R = i_R v_R = i_R^2 R \tag{36.33}$$

We can use $i_R = I_R \cos\omega t$ to write the resistor's instantaneous power loss as

$$p_R = i_R^2 R = I_R^2 R \cos^2\omega t \tag{36.34}$$

FIGURE 36.21 shows the instantaneous power graphically. You can see that, because the cosine is squared, the power oscillates twice during every cycle of the emf. The energy dissipation peaks both when $i_R = I_R$ and when $i_R = -I_R$.

In practice, we're more interested in the *average power* than in the instantaneous power. The **average power** P is the total energy dissipated per second. We can find P_R for a resistor by using the identity $\cos^2(x) = \frac{1}{2}(1 + \cos 2x)$ to write

$$P_R = I_R^2 R\cos^2\omega t = I_R^2 R\left[\frac{1}{2}(1 + \cos 2\omega t)\right] = \frac{1}{2}I_R^2 R + \frac{1}{2}I_R^2 R\cos 2\omega t$$

The $\cos 2\omega t$ term oscillates positive and negative twice during each cycle of the emf. Its average, over one cycle, is zero. Thus the average power loss in a resistor is

$$P_R = \frac{1}{2}I_R^2 R \quad \text{(average power loss in a resistor)} \tag{36.35}$$

It is useful to write Equation 36.35 as

$$P_R = \left(\frac{I_R}{\sqrt{2}}\right)^2 R = (I_{rms})^2 R \tag{36.36}$$

where the quantity

$$I_{rms} = \frac{I_R}{\sqrt{2}} \tag{36.37}$$

is called the **root-mean-square current,** or rms current, I_{rms}. Technically, an rms quantity is the square root of the average, or mean, of the quantity squared. For a sinusoidal oscillation, the rms value turns out to be the peak value divided by $\sqrt{2}$.

The rms current allows us to compare Equation 36.36 directly to the energy dissipated by a resistor in a DC circuit: $P = I^2R$. You can see that the average power loss of a resistor in an AC circuit with $I_{rms} = 1$ A is the same as in a DC circuit with $I = 1$ A. **As far as power is concerned, an rms current is equivalent to an equal DC current.**

The power rating on a lightbulb is its average power at $V_{rms} = 120$ V.

Similarly, we can define the root-mean-square voltage and emf:

$$V_{rms} = \frac{V_R}{\sqrt{2}} \qquad \mathcal{E}_{rms} = \frac{\mathcal{E}_0}{\sqrt{2}} \tag{36.38}$$

The resistor's average power loss in terms of the rms quantities is

$$P_R = (I_{rms})^2 R = \frac{(V_{rms})^2}{R} = I_{rms}V_{rms} \tag{36.39}$$

and the average power supplied by the emf is

$$P_{source} = I_{rms}\mathcal{E}_{rms} \tag{36.40}$$

The single-resistor circuit that we analyzed in Section 36.1 had $V_R = \mathcal{E}$ or, equivalently, $V_{rms} = \mathcal{E}_{rms}$. You can see from Equations 36.39 and 36.40 that the power loss in the resistor exactly matches the power supplied by the emf. This must be the case in order to conserve energy.

NOTE ▶ Voltmeters, ammeters, and other AC measuring instruments are calibrated to give the rms value. An AC voltmeter would show that the "line voltage" of an electrical outlet in the United States is 120 V. This is $\mathcal{E}_{rms}$. The peak voltage $\mathcal{E}_0$ is larger by a factor of $\sqrt{2}$, or $\mathcal{E}_0 = 170$ V. The power-line voltage is sometimes specified as "120 V/60 Hz," showing the rms voltage and the frequency. ◀

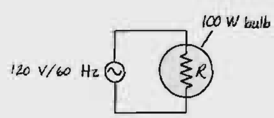
EXAMPLE 36.7 Lighting a bulb

A 100 W incandescent lightbulb is plugged into a 120 V/60 Hz outlet. What is the resistance of the bulb's filament? What is the peak current through the bulb?

MODEL The filament in a lightbulb acts as a resistor.

VISUALIZE FIGURE 36.22 is a simple one-resistor circuit.

FIGURE 36.22 An AC circuit with a lightbulb as a resistor.



SOLVE A bulb labeled 100 W is designed to dissipate an average 100 W at $V_{rms} = 120$ V. We can use Equation 36.39 to find

$$R = \frac{(V_{rms})^2}{P_{avg}} = \frac{(120\text{ V})^2}{100\text{ W}} = 144\ \Omega$$

The rms current is then found from

$$I_{rms} = \frac{P_{avg}}{V_{rms}} = \frac{100\text{ W}}{120\text{ V}} = 0.833\text{ A}$$

The peak current is $I_R = \sqrt{2}I_{rms} = 1.18$ A.

ASSESS Calculations with rms values are just like the calculations for DC circuits.

Capacitors and Inductors

In Section 36.2, we found that the instantaneous current to a capacitor is $i_C = -\omega C V_C \sin\omega t$. Thus the instantaneous energy dissipation in a capacitor is

$$p_C = v_C i_C = (V_C \cos\omega t)(-\omega C V_C \sin\omega t) = -\frac{1}{2}\omega C V_C^2 \sin 2\omega t \quad (36.41)$$

where we used $\sin(2x) = 2\sin(x)\cos(x)$.

FIGURE 36.23 shows Equation 36.41 graphically. Energy is transferred into the capacitor (positive power) as it is charged, but, instead of being dissipated, as it would be by a resistor, the energy is stored as potential energy in the capacitor's electric field. Then, as the capacitor discharges, this energy is given back to the circuit. Power is the rate at which energy is *removed* from the circuit, hence p is negative as the capacitor transfers energy back into the circuit.

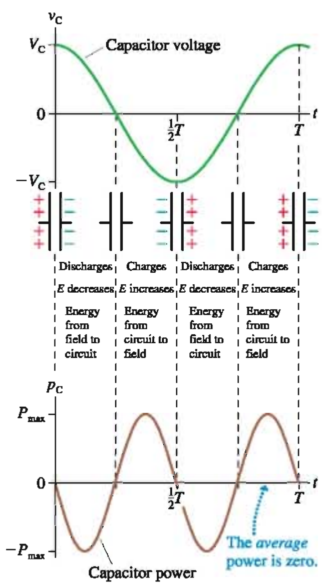


FIGURE 36.23 Energy flows into and out of a capacitor as it is charged and discharged.

Returning to our mechanical analogy, a capacitor is like an ideal, frictionless simple harmonic oscillator. Kinetic and potential energy are constantly being exchanged, but there is no dissipation because none of the energy is transformed into thermal energy. The important conclusion is that **a capacitor's average power loss is zero: $P_C = 0$.**

The same is true of an inductor. An inductor alternately stores energy in the magnetic field, as the current is increasing, then transfers energy back to the circuit as the current decreases. The instantaneous power oscillates between positive and negative, but **an inductor's average power loss is zero: $P_L = 0$.**

NOTE ► We're assuming ideal capacitors and inductors. Real capacitors and inductors inevitably have a small amount of resistance and dissipate a small amount of energy. However, their energy dissipation is negligible compared to that of the resistors in most practical circuits. ◄

The Power Factor

In an *RLC* circuit, energy is supplied by the emf and dissipated by the resistor. But an *RLC* circuit is unlike a purely resistive circuit in that the current is not in phase with the potential difference of the emf.

We found in Equation 36.22 that the instantaneous current in an *RLC* circuit is $i = I\cos(\omega t - \phi)$, where ϕ is the angle by which the current lags the emf. Thus the instantaneous power supplied by the emf is

$$p_{source} = i\mathcal{E} = (I\cos(\omega t - \phi))(\mathcal{E}_0 \cos\omega t) = I\mathcal{E}_0 \cos\omega t \cos(\omega t - \phi) \quad (36.42)$$

We can use the expression $\cos(x - y) = \cos(x)\cos(y) + \sin(x)\sin(y)$ to write the power as

$$p_{source} = (I\mathcal{E}_0 \cos\phi)\cos^2\omega t + (I\mathcal{E}_0 \sin\phi)\sin\omega t \cos\omega t \quad (36.43)$$

In our analysis of the power loss in a resistor and a capacitor, we found that the average of $\cos^2\omega t$ is $\frac{1}{2}$ and the average of $\sin\omega t\cos\omega t$ is zero. Thus we can immediately write that the *average* power supplied by the emf is

$$P_{source} = \frac{1}{2} I\mathcal{E}_0 \cos\phi = I_{rms}\mathcal{E}_{rms}\cos\phi \qquad (36.44)$$

The rms values, you will recall, are $I/\sqrt{2}$ and $\mathcal{E}_0/\sqrt{2}$.

The term $\cos\phi$, called the **power factor,** arises because the current and the emf in a series *RLC* circuit are not in phase. Because the current and the emf aren't pushing and pulling together, the source delivers less energy to the circuit.

We'll leave it as a homework problem for you to show that the peak current in an *RLC* circuit can be written $I = I_{max}\cos\phi$, where $I_{max} = \mathcal{E}_0/R$ was given in Equation 36.31. In other words, the current term in Equation 36.44 is a function of the power factor. Consequently, the average power is

$$P_{source} = P_{max}\cos^2\phi \qquad (36.45)$$

Industrial motors use a significant fraction of the electric energy generated in the United States.

where $P_{max} = \frac{1}{2} I_{max}\mathcal{E}_0$ is the *maximum* power the source can deliver to the circuit.

The source delivers maximum power only when $\cos\phi = 1$. This is the case when $X_L - X_C = 0$, requiring either a purely resistive circuit or an *RLC* circuit operating at the resonance frequency ω_0. The average power loss is zero for a purely capacitive or purely inductive load with, respectively, $\phi = -90°$ or $\phi = +90°$, as found above.

Motors of various types, especially large industrial motors, use a significant fraction of the electric energy generated in industrialized nations. Motors operate most efficiently, doing the maximum work per second, when the power factor is as close to 1 as possible. But motors are inductive devices, due to their electromagnet coils, and if too many motors are attached to the electric grid, the power factor is pulled away from 1. To compensate, the electric company places large capacitors throughout the transmission system. The capacitors dissipate no energy, but they allow the electric system to deliver energy more efficiently by keeping the power factor close to 1.

Finally, we found in Equation 36.28 that the resistor's peak voltage in an *RLC* circuit is related to the emf peak voltage by $V_R = \mathcal{E}_0\cos\phi$ or, dividing both sides by $\sqrt{2}$, $V_{rms} = \mathcal{E}_{rms}\cos\phi$. We can use this result to write the energy loss in the resistor as

$$P_R = I_{rms}V_{rms} = I_{rms}\mathcal{E}_{rms}\cos\phi \qquad (36.46)$$

But this expression is P_{source}, as we found in Equation 36.44. Thus we see that the energy supplied to an *RLC* circuit by the emf is ultimately dissipated by the resistor.

EXAMPLE 36.8 The power used by a motor

A motor attached to a 120 V/60 Hz power line uses 600 W of power at a power factor of 0.80.

a. What is the rms current to the motor?
b. What is the motor's resistance?

MODEL The motor has inductance. Otherwise, the power factor would be 1. Treat it as a series *RLC* circuit without the capacitor ($X_C = 0$).

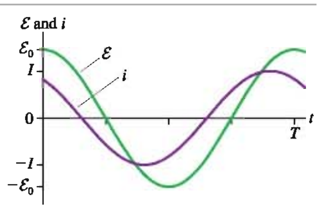
SOLVE a. The average power is $P_{source} = I_{rms}\mathcal{E}_{rms}\cos\phi$. Thus

$$I_{rms} = \frac{P_{avg}}{\mathcal{E}_{rms}\cos\phi} = \frac{600\text{ W}}{(120\text{ V})(0.80)} = 6.25\text{ A}$$

b. We can use $V_{rms} = \mathcal{E}_{rms}\cos\phi$ and Ohm's law to find that the resistance is

$$R = \frac{V_{rms}}{I_{rms}} = \frac{\mathcal{E}_{rms}\cos\phi}{I_{rms}} = \frac{(120\text{ V})(0.80)}{6.25\text{ A}} = 15.4\ \Omega$$

STOP TO THINK 36.6 The emf and the current in a series *RLC* circuit oscillate as shown. Which of the following (perhaps more than one) would increase the rate at which energy is supplied to the circuit?



a. Increase $\mathcal{E}_0$
b. Increase L
c. Increase C
d. Decrease $\mathcal{E}_0$
e. Decrease L
f. Decrease C

SUMMARY

The goal of Chapter 36 has been to understand and apply basic techniques of AC circuit analysis.

Important Concepts

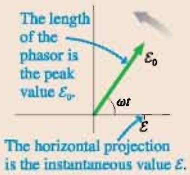
AC circuits

AC circuits are driven by an emf

$$\mathcal{E} = \mathcal{E}_0 \cos\omega t$$

that oscillates with angular frequency $\omega = 2\pi f$.

Phasors can be used to represent the oscillating emf, current, and voltage.



Basic circuit elements

Element	i and v	Resistance/ reactance	I and V	Power
Resistor	In phase	R is fixed	$V = IR$	$V_{rms}I_{rms}$
Capacitor	i leads v by 90°	$X_C = 1/\omega C$	$V = IX_C$	0
Inductor	i lags v by 90°	$X_L = \omega L$	$V = IX_L$	0

For many purposes, especially calculating power, the **root-mean-square** (rms) quantities

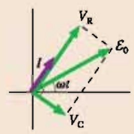
$$V_{rms} = V/\sqrt{2} \qquad I_{rms} = I/\sqrt{2} \qquad \mathcal{E}_{rms} = \mathcal{E}_0/\sqrt{2}$$

are equivalent to the corresponding DC quantities.

Key Skills

Phasor diagrams

- Start with a phasor (v or i) common to two or more circuit elements.
- The sum of instantaneous quantities is vector addition.
- Use the Pythagorean theorem to relate peak quantities.



For an RC circuit, shown here,

$$v_R + v_C = \mathcal{E}$$
$$V_R^2 + V_C^2 = \mathcal{E}_0^2$$

Kirchhoff's laws

Loop law The sum of the potential differences around a loop is zero.

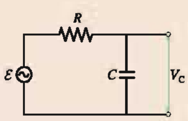
Junction law The sum of currents entering a junction equals the sum leaving the junction.

Instantaneous and peak quantities

Instantaneous quantities v and i generally obey different relationships than peak quantities V and I.

Applications

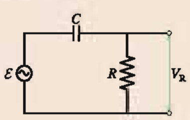
RC filter circuits



$$V_C = \mathcal{E}_0 X_C/\sqrt{R^2 + X_C^2}$$

$$V_C \to \mathcal{E}_0 \text{ as } \omega \to 0$$

A **low-pass filter** transmits low frequencies and blocks high frequencies.

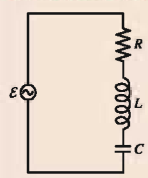


$$V_R = \mathcal{E}_0 R/\sqrt{R^2 + X_C^2}$$

$$V_R \to \mathcal{E}_0 \text{ as } \omega \to \infty$$

A **high-pass filter** transmits high frequencies and blocks low frequencies.

Series RLC circuits



$I = \mathcal{E}_0/Z$ where Z is the **impedance**

$$Z = \sqrt{R^2 + (X_L - X_C)^2}$$

$$V_R = IR \qquad V_L = IX_L \qquad V_C = IX_C$$

When $\omega = \omega_0 = 1/\sqrt{LC}$ (the **resonance frequency**), the current in the circuit is a maximum $I_{max} = \mathcal{E}_0/R$.

In general, the current i lags behind $\mathcal{E}$ by the **phase angle** $\phi = \tan^{-1}((X_L - X_C)/R)$.

The power supplied by the emf is $P_{source} = I_{rms}\mathcal{E}_{rms}\cos\phi$, where $\cos\phi$ is called the **power factor.**

The power lost in the resistor is $P_R = I_{rms}V_{rms} = (I_{rms})^2R$.

Terms and Notation

AC circuit	crossover frequency, ω_c	series RLC circuit	root-mean-square current, I_{rms}
DC circuit	low-pass filter	impedance, Z	power factor, $\cos\phi$
phasor	high-pass filter	resonance frequency, ω_0	
capacitive reactance, X_C	inductive reactance, X_L	average power, P

Problem difficulty is labeled as | (straightforward) to ||| (challenging).

Problems labeled integrate significant material from earlier chapters.

CONCEPTUAL QUESTIONS

1. FIGURE Q36.1 shows emf phasors a, b, and c.
   a. For each, what is the instantaneous value of the emf?
   b. At this instant, is the magnitude of each emf increasing, decreasing, or holding constant?

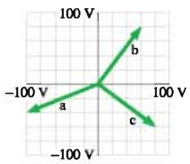

FIGURE Q36.1

2. The peak current through a resistor is 2.0 A. What is the peak current if:
   a. The resistance R is doubled?
   b. The peak emf $\mathcal{E}_0$ is doubled?
   c. The frequency ω is doubled?
3. The peak current through a capacitor is 2.0 A. What is the peak current if:
   a. The capacitance C is doubled?
   b. The peak emf $\mathcal{E}_0$ is doubled?
   c. The frequency ω is doubled?
4. A low-pass RC filter has a crossover frequency $f_c = 200$ Hz. What is f_c if:
   a. The resistance R is doubled?
   b. The capacitance C is doubled?
   c. The peak emf $\mathcal{E}_0$ is doubled?
5. The peak current passing through an inductor is 2.0 A. What is the peak current if:
   a. The inductance L is doubled?
   b. The peak emf $\mathcal{E}_0$ is doubled?
   c. The frequency ω is doubled?
6. The resonance frequency of a series RLC circuit is 1000 Hz. What is the resonance frequency if:
   a. The resistance R is doubled?
   b. The inductance L is doubled?
   c. The capacitance C is doubled?
   d. The peak emf $\mathcal{E}_0$ is doubled?
7. In the series RLC circuit represented by the phasors of FIGURE Q36.7, is the emf frequency less than, equal to, or greater than the resonance frequency ω_0? Explain.

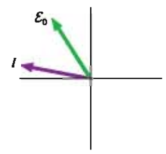

FIGURE Q36.7

8. The resonance frequency of a series RLC circuit is less than the emf frequency. Does the current lead or lag the emf? Explain.
9. The current in a series RLC circuit lags the emf by 20°. You cannot change the emf. What two different things could you do to the circuit that would increase the power delivered to the circuit by the emf?
10. The average power dissipated by a resistor is 4.0 W. What is P_{avg} if:
    a. The resistance R is doubled?
    b. The peak emf $\mathcal{E}_0$ is doubled?
    c. Both are doubled simultaneously?

EXERCISES AND PROBLEMS

Exercises

Section 36.1 AC Sources and Phasors

1. | The emf phasor in FIGURE EX36.1 is shown at $t = 15$ ms.
   a. What is the angular frequency ω? Assume this is the first rotation.
   b. What is the instantaneous value of the emf?

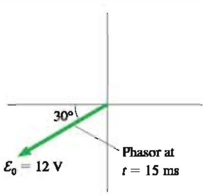

FIGURE EX36.1

2. | The emf phasor in FIGURE EX36.2 is shown at $t = 2.0$ ms.
   a. What is the angular frequency ω? Assume this is the first rotation.
   b. What is the peak value of the emf?

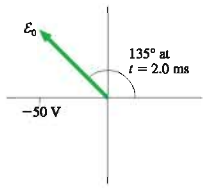

FIGURE EX36.2

3. | A 110 Hz source of emf has a peak voltage of 50 V. Draw the emf phasor at $t = 3.0$ ms.
4. | Draw the phasor for the emf $\mathcal{E} = (170\text{ V})\cos\big((2\pi \times 60\text{ Hz})t\big)$ at $t = 60$ ms.
5. | A 200 Ω resistor is connected to an AC source with $\mathcal{E}_0 = 10$ V. What is the peak current through the resistor if the emf frequency is (a) 100 Hz? (b) 100 kHz?
6. | FIGURE EX36.6 shows voltage and current graphs for a resistor.
   a. What is the emf frequency f?
   b. What is the value of the resistance R?
   c. Draw the resistor's voltage and current phasors at $t = 15$ ms.

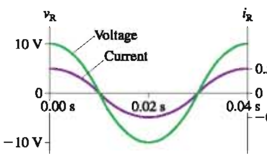

FIGURE EX36.6

Section 36.2 Capacitor Circuits

7. || A 0.30 μF capacitor is connected across an AC generator that produces a peak voltage of 10 V. What is the peak current to and from the capacitor if the emf frequency is (a) 100 Hz? (b) 100 kHz?
8. | The peak current to and from a capacitor is 10 mA. What is the peak current if
   a. The emf frequency is doubled?
   b. The emf peak voltage is doubled (at the original frequency)?
   c. The frequency is halved and, at the same time, the emf is doubled?
9. || A 20 nF capacitor is connected across an AC generator that produces a peak voltage of 5.0 V.
   a. At what frequency f is the peak current 50 mA?
   b. What is the instantaneous value of the emf at the instant when $i_C = I_C$?
10. || A capacitor is connected to a 15 kHz oscillator. The peak current is 65 mA when the rms voltage is 6.0 V. What is the value of the capacitance C?
11. || A capacitor has a peak current of 330 μA when the peak voltage at 250 kHz is 2.2 V.
   a. What is the capacitance?
   b. If the voltage is held constant, what is the peak current at 500 kHz?

Section 36.3 *RC* Filter Circuits

12. | A high-pass *RC* filter is connected to an AC source with a peak voltage of 10.0 V. The peak capacitor voltage is 6.0 V. What is the resistor voltage?
13. | A low-pass *RC* filter with a crossover frequency of 1000 Hz uses a 100 Ω resistor. What is the value of the capacitor?
14. | A high-pass *RC* filter with a crossover frequency of 1000 Hz uses a 100 Ω resistor. What is the value of the capacitor?
15. || What are V_R and V_C if the emf frequency in FIGURE EX36.15 is 10 kHz?

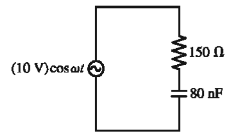

FIGURE EX36.15

16. | A high-pass filter consists of a 1.59 μF capacitor in series with a 100 Ω resistor. The circuit is driven by an AC source with a peak voltage of 5.00 V.
   a. What is the crossover frequency f_c?
   b. What is V_R when $f = \frac{1}{2}f_c$, f_c, and $2f_c$?
17. | A low-pass filter consists of a 100 μF capacitor in series with a 159 Ω resistor. The circuit is driven by an AC source with a peak voltage of 5.00 V.
   a. What is the crossover frequency f_c?
   b. What is V_C when $f = \frac{1}{2}f_c$, f_c, and $2f_c$?

Section 36.4 Inductor Circuits

18. | The peak current through an inductor is 10 mA. What is the peak current if
   a. The emf frequency is doubled?
   b. The emf peak voltage is doubled (at the original frequency)?
   c. The frequency is halved and, at the same time, the emf is doubled?
19. || A 20 mH inductor is connected across an AC generator that produces a peak voltage of 10 V. What is the peak current through the inductor if the emf frequency is (a) 100 Hz? (b) 100 kHz?
20. || An inductor is connected to a 15 kHz oscillator. The peak current is 65 mA when the rms voltage is 6.0 V. What is the value of the inductance L?
21. | A 500 μH inductor is connected across an AC generator that produces a peak voltage of 5.0 V.
   a. At what frequency f is the peak current 50 mA?
   b. What is the instantaneous value of the emf at the instant when $i_L = I_L$?
22. || An inductor has a peak current of 330 μA when the peak voltage at 45 MHz is 2.2 V.
   a. What is the inductance?
   b. If the voltage is held constant, what is the peak current at 90 MHz?

Section 36.5 The Series *RLC* Circuit

23. || A series *RLC* circuit has a 200 kHz resonance frequency. What is the resonance frequency if
   a. The resistor value is doubled?
   b. The capacitor value is doubled?

24. | A series RLC circuit has a 200 kHz resonance frequency. What is the resonance frequency if
    a. The resistor value is doubled?
    b. The capacitor value is doubled and, at the same time, the inductor value is halved?
25. || What capacitor in series with a 100 Ω resistor and a 20 mH inductor will give a resonance frequency of 1000 Hz?
26. || What inductor in series with a 100 Ω resistor and a 2.5 μF capacitor will give a resonance frequency of 1000 Hz?
27. | A series RLC circuit consists of a 50 Ω resistor, a 3.3 mH inductor, and a 480 nF capacitor. It is connected to an oscillator with a peak voltage of 5.0 V. Determine the impedance, the peak current, and the phase angle at frequencies (a) 3000 Hz, (b) 4000 Hz, and (c) 5000 Hz.
28. | At what frequency f do a 1.0 μF capacitor and a 1.0 μH inductor have the same reactance? What is the value of the reactance at this frequency?

Section 36.6 Power in AC Circuits

29. | The heating element of a hair drier dissipates 1500 W when connected to a 120 V/60 Hz power line. What is its resistance?
30. | A 100 Ω resistor is connected to a 120 V/60 Hz power line. What is its average power loss?
31. | The motor of an electric drill draws a 3.5 A current at the power-line voltage of 120 V rms. What is the motor's power if the current lags the voltage by 20°?
32. || A resistor dissipates 2.0 W when the rms voltage of the emf is 10.0 V. At what rms voltage will the resistor dissipate 10.0 W?
33. || A series RLC circuit attached to a 120 V/60 Hz power line draws 2.4 A of current with a power factor of 0.87. What is the value of the resistor?
34. || A series RLC circuit with a 100 Ω resistor dissipates 80 W when attached to a 120 V/60 Hz power line. What is the power factor?

Problems

35. || a. For an RC circuit, find an expression for the angular frequency ω_{res} at which $V_R = \frac{1}{2}\mathcal{E}_0$.
    b. What is V_C at this frequency?
    c. What is ω_{res} if the crossover frequency is 6280 rad/s?
36. || a. For an RC circuit, find an expression for the angular frequency ω_{cap} at which $V_C = \frac{1}{2}\mathcal{E}_0$.
    b. What is V_R at this frequency?
    c. What is ω_{cap} if the crossover frequency is 6280 rad/s?
37. || a. Evaluate V_C in FIGURE P36.37 at emf frequencies 1, 3, 10, 30, and 100 kHz.
    b. Graph V_C versus frequency. Draw a smooth curve through your five points.

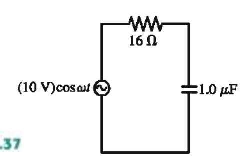

FIGURE P36.37

38. || a. Evaluate V_R in FIGURE P36.38 at emf frequencies 100, 300, 1000, 3000, and 10,000 Hz.
    b. Graph V_R versus frequency. Draw a smooth curve through your five points.

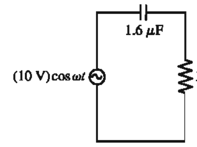

FIGURE P36.38

39. || For an RC filter circuit, show that $V_R = V_C = \mathcal{E}_0/\sqrt{2}$ at $\omega = \omega_c$.
40. || When two capacitors are connected in parallel across a 10.0 V rms, 1.00 kHz oscillator, the oscillator supplies a total rms current of 545 mA. When the same two capacitors are connected to the oscillator in series, the oscillator supplies an rms current of 126 mA. What are the values of the two capacitors?
41. || Show that Equation 36.27 for the phase angle ϕ of a series RLC circuit gives the correct result for a capacitor-only circuit.
42. || a. What is the peak current supplied by the emf in FIGURE P36.42?
    b. What is the peak voltage across the 3.0 μF capacitor?

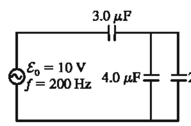

FIGURE P36.42

43. || You have a resistor and a capacitor of unknown values. First, you charge the capacitor and discharge it through the resistor. By monitoring the capacitor voltage on an oscilloscope, you see that the voltage decays to half its initial value in 2.5 ms. You then use the resistor and capacitor to make a low-pass filter. What is the crossover frequency f_c?
44. || FIGURE P36.44 shows a parallel RC circuit.
    a. Use a phasor-diagram analysis to find expressions for the peak currents I_R and I_C. **Hint:** What do the resistor and capacitor have in common? Use that as the initial phasor.
    b. Complete the phasor analysis by finding an expression for the peak emf current I.

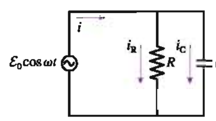

FIGURE P36.44

45. || FIGURE P36.45 shows voltage and current graphs for a capacitor.
    a. What is the emf frequency f?
    b. What is the value of the capacitance C?
    c. Draw the capacitor's voltage and current phasors at $t = 7.5$ ms.

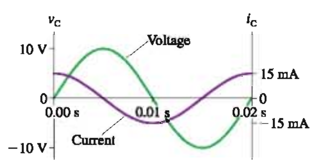

FIGURE P36.45

46. || FIGURE P36.46 shows voltage and current graphs for an inductor.
 a. What is the emf frequency f?
 b. What is the value of the inductance L?
 c. Draw the inductor's voltage and current phasors at $t = 7.5$ ms.

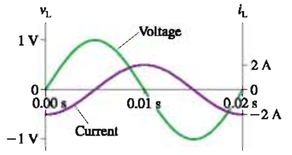

FIGURE P36.46

47. || Use a phasor diagram to analyze the RL circuit of FIGURE P36.47. In particular,
 a. Find expressions for I, V_R, and V_L.
 b. What is V_R in the limits $\omega \to 0$ and $\omega \to \infty$?
 c. If the output is taken from the resistor, is this a low-pass or a high-pass filter? Explain.
 d. Find an expression for the crossover frequency ω_c.

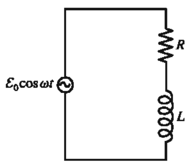

FIGURE P36.47

48. || A series RLC circuit consists of a 100 Ω resistor, a 0.10 H inductor, and a 100 μF capacitor. It is attached to a 120 V/60 Hz power line. What are (a) the peak current I, (b) the phase angle ϕ, and (c) the average power loss?

49. || A series RLC circuit consists of a 100 Ω resistor, a 0.15 H inductor, and a 30 μF capacitor. It is attached to a 120 V/60 Hz power line. What are (a) the peak current I, (b) the phase angle ϕ, and (c) the average power loss?

50. || For the circuit of FIGURE P36.50,
 a. What is the resonance frequency, in both rad/s and Hz?
 b. Find V_R and V_L at resonance.
 c. How can V_L be larger than $\mathcal{E}_0$? Explain.

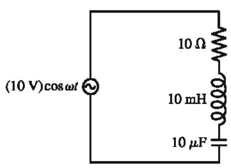

FIGURE P36.50

51. || For the circuit of FIGURE P36.51,
 a. What is the resonance frequency, in both rad/s and Hz?
 b. Find V_R and V_C at resonance.
 c. How can V_C be larger than $\mathcal{E}_0$? Explain.

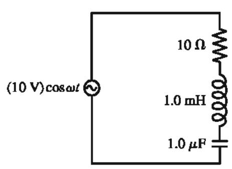

FIGURE P36.51

52. || In FIGURE P36.52, what is the current supplied by the emf when (a) the frequency is very small and (b) the frequency is very large?

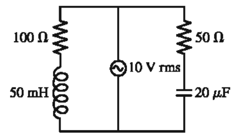

FIGURE P36.52

53. || The current lags the emf by 30° in a series RLC circuit with $\mathcal{E}_0 = 10$ V and $R = 50\ \Omega$. What is the peak current through the circuit?

54. || A series RLC circuit consists of a 50 Ω resistor, a 3.3 mH inductor, and a 480 nF capacitor. It is connected to a 5.0 kHz oscillator with a peak voltage of 5.0 V. What is the instantaneous current i when
 a. $\mathcal{E} = \mathcal{E}_0$?
 b. $\mathcal{E} = 0$ V and is decreasing?

55. || A series RLC circuit consists of a 50 Ω resistor, a 3.3 mH inductor, and a 480 nF capacitor. It is connected to a 3.0 kHz oscillator with a peak voltage of 5.0 V. What is the instantaneous emf $\mathcal{E}$ when
 a. $i = I$?
 b. $i = 0$ A and is decreasing?
 c. $i = -I$?

56. || A series RLC circuit consists of a 100 Ω resistor, a 10 mH inductor, and a 1.0 nF capacitor. It is connected to an oscillator with an rms voltage of 10 V. What is the power supplied to the circuit if (a) $\omega = \frac{1}{2}\omega_0$? (b) $\omega = \omega_0$? (c) $\omega = 2\omega_0$?

57. || Show that the impedance of a series RLC circuit can be written

$$Z = \sqrt{R^2 + \omega^2 L^2 (1 - \omega_0^2/\omega^2)^2}$$

58. || For a series RLC circuit, show that
 a. The peak current can be written $I = I_{max}\cos\phi$.
 b. The average power dissipation can be written $P_{avg} = P_{max}\cos^2\phi$.

59. || The tuning circuit in an FM radio receiver is a series RLC circuit with a 0.200 μH inductor.
 a. The receiver is tuned to a station at 104.3 MHz. What is the value of the capacitor in the tuning circuit?
 b. FM radio stations are assigned frequencies every 0.2 MHz, but two nearby stations cannot use adjacent frequencies. What is the maximum resistance the tuning circuit can have if the peak current at a frequency of 103.9 MHz, the closest frequency that can be used by a nearby station, is to be no more than 0.10% of the peak current at 104.3 MHz? The radio is still tuned to 104.3 MHz, and you can assume the two stations have equal strength.

60. || A television channel is assigned the frequency range from 54 MHz to 60 MHz. A series RLC tuning circuit in a TV receiver resonates in the middle of this frequency range. The circuit uses a 16 pF capacitor.
 a. What is the value of the inductor?
 b. In order to function properly, the current throughout the frequency range must be at least 50% of the current at the resonance frequency. What is the minimum possible value of the circuit's resistance?

61. || Lightbulbs labeled 40 W, 60 W, and 100 W are connected to a 120 V/60 Hz power line as shown in FIGURE P36.61. What is the rate at which energy is dissipated in each bulb?

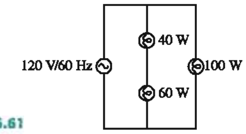

FIGURE P36.61

62. || Commercial electricity is generated and transmitted as *three-phase electricity.* Instead of a single emf, three separate wires carry currents for the emfs $\mathcal{E}_1 = \mathcal{E}_0\cos\omega t$, $\mathcal{E}_2 = \mathcal{E}_0\cos(\omega t + 120°)$, and $\mathcal{E}_3 = \mathcal{E}_0\cos(\omega t - 120°)$ over three parallel wires, each of which supplies one-third of the power. This is why the long-distance transmission lines you see in the countryside have three wires. Suppose the transmission lines into a city supply a total of 450 MW of electric power, a realistic value.
   a. What would be the current in each wire if the transmission voltage were $\mathcal{E}_0 = 120$ V rms?
   b. In fact, transformers are used to step the transmission-line voltage up to 500 kV rms. What is the current in each wire?
   c. Big transformers are expensive. Why does the electric company use step-up transformers?

63. || A motor attached to a 120 V/60 Hz power line draws an 8.0 A current. Its average energy dissipation is 800 W.
   a. What is the power factor?
   b. What is the rms resistor voltage?
   c. What is the motor's resistance?
   d. How much series capacitance needs to be added to increase the power factor to 1.0?

64. || You're the operator of a 15,000 V rms, 60 Hz electrical substation. When you get to work one day, you see that the station is delivering 6.0 MW of power with a power factor of 0.90.
   a. What is the rms current leaving the station?
   b. How much series capacitance should you add to bring the power factor up to 1.0?
   c. How much power will the station then be delivering?

Challenge Problems

65. The small transformers that power many consumer products produce a 12.0 V rms, 60 Hz emf. Design a circuit using resistors and capacitors that uses the transformer voltage as an input and produces a 6.0 V rms output that leads the input voltage by 45°.

66. Commercial electricity is generated and transmitted as *three-phase electricity.* Instead of a single emf $\mathcal{E} = \mathcal{E}_0\cos\omega t$, three separate wires carry currents for the emfs $\mathcal{E}_1 = \mathcal{E}_0\cos\omega t$, $\mathcal{E}_2 = \mathcal{E}_0\cos(\omega t + 120°)$, and $\mathcal{E}_3 = \mathcal{E}_0\cos(\omega t - 120°)$. This is why the long-distance transmission lines you see in the countryside have three parallel wires, as do many distribution lines within a city.
   a. Draw a phasor diagram showing phasors for all three phases of a three-phase emf.
   b. Show that the sum of the three phases is zero, producing what is referred to as *neutral.* In *single-phase* electricity, provided by the familiar 120 V/60 Hz electric outlets in your home, one side of the outlet is neutral, as established at a nearby electrical substation. The other, called the *hot side,* is one of the three phases. (The round opening is connected to ground.)
   c. Show that the potential difference between any two of the phases has the rms value $\sqrt{3}\mathcal{E}_{rms}$, where $\mathcal{E}_{rms}$ is the familiar single-phase rms voltage. Evaluate this potential difference for $\mathcal{E}_{rms} = 120$ V. Some high-power home appliances, especially electric clothes dryers and hot-water heaters, are designed to operate between two of the phases rather than between one phase and neutral. Heavy-duty industrial motors are designed to operate from all three phases, but full three-phase power is rare in residential or office use.

67. FIGURE CP36.67 shows voltage and current graphs for a series *RLC* circuit.
   a. What is the resistance *R*?
   b. If $L = 200\ \mu$H, what is the resonance frequency?

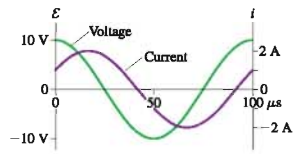

FIGURE CP36.67

68. a. Show that the average power loss in a series *RLC* circuit is

$$P_{avg} = \frac{\omega^2 \mathcal{E}_{rms}^{\,2} R}{\omega^2 R^2 + L^2(\omega^2 - \omega_0^2)^2}$$

   b. Prove that the energy dissipation is a maximum at $\omega = \omega_0$.

69. a. Show that the peak inductor voltage in a series *RLC* circuit is maximum at frequency

$$\omega_L = \left(\frac{1}{\omega_0^2} - \frac{1}{2}R^2C^2\right)^{-1/2}$$

   b. A series *RLC* circuit with $\mathcal{E}_0 = 10.0$ V consists of a 1.0 Ω resistor, a 1.0 μH inductor, and a 1.0 μF capacitor. What is V_L at $\omega = \omega_0$ and at $\omega = \omega_L$?

70. The telecommunication circuit shown in FIGURE CP36.70 has a parallel inductor and capacitor in series with a resistor.
   a. Use a phasor diagram to show that the peak current through the resistor is

$$I = \frac{\mathcal{E}_0}{\sqrt{R^2 + \left(\frac{1}{X_L} - \frac{1}{X_C}\right)^{-2}}}$$

   Hint: Start with the inductor phasor v_L.
   b. What is *I* in the limits $\omega \to 0$ and $\omega \to \infty$?
   c. What is the resonance frequency ω_0? What is *I* at this frequency?

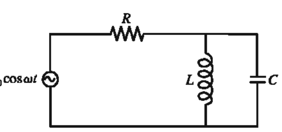

FIGURE CP36.70

71. Consider the parallel RLC circuit shown in FIGURE CP36.71.
   a. Show that the current drawn from the emf is

$$I = \mathcal{E}_0\sqrt{\frac{1}{R^2} + \left(\frac{1}{\omega L} - \omega C\right)^2}$$

   Hint: Start with a phasor that is common to all three circuit elements.
   b. What is I in the limits $\omega \to 0$ and $\omega \to \infty$?
   c. Find the frequency for which I is a minimum.
   d. Sketch a graph of I versus ω.

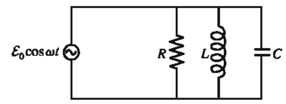

FIGURE CP36.71

STOP TO THINK ANSWERS

Stop to Think 36.1: a. The instantaneous emf value is the projection down onto the horizontal axis. The emf is negative but increasing in magnitude as the phasor, which rotates ccw, approaches the horizontal axis.

Stop to Think 36.2: c. Voltage and current are measured using different scales and units. You can't compare the length of a voltage phasor to the length of a current phasor.

Stop to Think 36.3: a. There is "no capacitor" when the separation between the two capacitor plates becomes zero and the plates touch. Capacitance C is inversely proportional to the plate spacing d, hence $C \to \infty$ as $d \to 0$. The capacitive reactance is inversely proportional to C, so $X_C \to 0$ as $C \to \infty$.

Stop to Think 36.4: $(\omega_c)_d > (\omega_c)_c = (\omega_c)_a > (\omega_c)_b$. The crossover frequency is $1/RC$.

Stop to Think 36.5: Above. $V_L > V_C$ tells us that $X_L > X_C$. This is the condition above resonance, where X_L is increasing with ω while X_C is decreasing.

Stop to Think 36.6: a, b, and f. You can always increase power by turning up the voltage. The current leads the emf, telling us that the circuit is primarily capacitive. The current can be brought into phase with the emf, thus maximizing the power, by decreasing C or increasing L.

PART

VI SUMMARY Electricity and Magnetism

Mass and charge are the two most fundamental properties of matter. The first five parts of this text were investigations of the properties and interactions of masses. Part VI has been a study of the physics of charge—what charge is and how charges interact.

Electric and magnetic fields were introduced to enable us to understand the long-range forces of electricity and magnetism. The field concept is subtle, but it is an essential part of our modern understanding of the physical universe. One charge—the source charge—alters the space around it by creating an electric field and, if the charge is moving, a magnetic field. Other charges experience forces exerted *by the fields*. Thus the electric and magnetic fields are the agents by which charges interact.

Faraday's discovery of electromagnetic induction led scientists to recognize that the fields are *real* and can exist independently of charges. The most vivid confirmation of this reality was Maxwell's discovery of electromagnetic waves—the quintessential electromagnetic phenomenon.

Part VI has introduced many new phenomena, concepts, and laws. The knowledge structure table draws together the major ideas about charges and fields, and it briefly summarizes some of the most important applications of electricity and magnetism.

KNOWLEDGE STRUCTURE VI Electricity and Magnetism

ESSENTIAL CONCEPTS	Charge, dipole, field, potential, emf	
BASIC GOALS	How do charged particles interact? What are the properties and characteristics of electromagnetic fields?	
GENERAL PRINCIPLES	**Coulomb's law**	$\vec{E}_{\text{point charge}} = \dfrac{1}{4\pi\epsilon_0}\dfrac{q}{r^2}\hat{r} = \left(\dfrac{1}{4\pi\epsilon_0}\dfrac{q}{r^2}, \text{ away from } q\right)$
	Biot-Savart law	$\vec{B}_{\text{point charge}} = \dfrac{\mu_0}{4\pi}\dfrac{q\vec{v}\times\hat{r}}{r^2} = \left(\dfrac{\mu_0}{4\pi}\dfrac{qv\sin\theta}{r^2}, \text{ direction of right-hand rule}\right)$
	Faraday's law	$\mathcal{E} = \lvert d\Phi_m/dt\rvert$ $\quad I_{\text{induced}} = \mathcal{E}/R$ in the direction of Lenz's law
	Lenz's law	An induced current flows around a conducting loop in the direction such that the induced magnetic field opposes the *change* in the magnetic flux.
	Lorentz force law	$\vec{F}_{\text{on } q} = q(\vec{E} + \vec{v}\times\vec{B})$
	Superposition	The electric or magnetic field due to multiple charges is the vector sum of the field of each charge. This principle was used to derive the fields of many special charge distributions, such as wires, planes, and loops.

FIELD AND POTENTIAL The electric field of charges can also be described in terms of an electric potential V:

$$V_{\text{point charge}} = \frac{q}{4\pi\epsilon_0 r}$$

- The electric field is perpendicular to equipotential surfaces and in the direction of decreasing potential.
- The potential energy of charge q is $U = qV$. The total energy $K + qV$ of a group of charges is conserved.

ELECTROMAGNETIC WAVES All the properties of electromagnetic fields are summarized mathematically in four equations called *Maxwell's equations.* From Maxwell's equations we learn that electromagnetic fields can exist independently of charges as an *electromagnetic wave.*

- An em wave travels at speed $c = 1/\sqrt{\epsilon_0\mu_0}$.
- $\vec{E}$ and $\vec{B}$ are perpendicular to each other and to the direction of travel, with $E = cB$.

Electric and magnetic properties of materials

- Charges move through conductors but not through insulators.
- Conductors and insulators are *polarized* in an electric field.
- A magnetic moment in a magnetic field experiences a torque.

Model of current and conductivity

- The charge carriers in metals are electrons.
- emf $\rightarrow$ electric field $\rightarrow$ current density $J = \sigma E \rightarrow I = JA$

Applications to circuits

- Circuits obey Kirchhoff's loop law (conservation of energy) and junction law (conservation of current).
- Resistors control the current: $I = \Delta V/R$ (Ohm's law).
- Capacitors store charge $Q = C\Delta V$ and energy $V_C = \frac{1}{2}C(\Delta V_C)^2$.

ONE STEP BEYOND

The Telecommunications Revolution

In 1800, the year that Alessandro Volta invented the battery and Thomas Jefferson was elected president, the fastest a message could travel was the speed of a man or woman on horseback. News took three days to travel from New York to Boston, and well over a month to reach the frontier outpost of Cincinnati.

But Hans Oersted's 1820 discovery that a current creates a magnetic field introduced revolutionary changes to communications. The American scientist Joseph Henry, who shares with Faraday credit for the discovery of electromagnetic induction, saw a simple electromagnet in 1825. Inspired, he set about improving the device. By 1830, Henry was able to send current through more than a mile of wire to activate an electromagnet and strike a bell.

In 1835, Henry met an entrepreneur interested in the commercial development of electric technology—Samuel F. B. Morse. Morse was one of the most prominent American artists of the early 19th century, but he also had an abiding interest in technology. In the 1830s, he invented the famous code that bears his name—Morse code—and began to experiment with electromagnets.

With advice and encouragement from Henry, Morse developed the first practical telegraph. The first telegraph line, between Washington, D.C., and Baltimore, began operating in 1844; the first message sent was, "What hath God wrought?" For the first time, long-distance communications could take place essentially instantaneously.

Telegraph communication advanced as quickly as wire could be strung, and a worldwide network had been established by 1875. But the telegraph didn't hold its monopoly for long, as other inventors began to think about using electromagnetic devices to transmit speech. The first to succeed was Alexander Graham Bell, who invented the telephone in 1876.

The telegraph and telephone provided electromagnetic communication over wires, but the discovery of electromagnetic waves opened up another possibility—wireless communication at the speed of light. Radio technology developed rapidly in the late 19th century, and in 1901 the Italian inventor Guglielmo Marconi sent and received the first transatlantic radio message. World War I prompted further development of radio, because of the need to communicate with military units as they moved about, and by 1925 more than 1000 radio stations were operating in the United States.

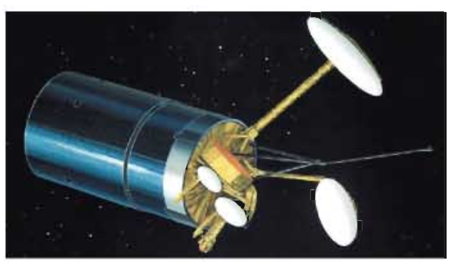
Radio and, later, television spanned the globe by 1960, but radio stations reached a few hundred miles at best, and television transmission was limited to each city. National broadcasts within the United States required the signal to be transmitted via microwave relays to local stations for rebroadcast. Network television shows were possible, but not live-from-the-scene broadcasts. Journalists had to film events, then return the film to the studio for broadcast. Television images from overseas could only be seen the next day, after film was flown back to the United States.

The first communications satellite was launched by NASA in 1960, followed two years later by a more practical satellite, Telstar, that used solar power to amplify signals received from earth and beam them back down. The first live transatlantic television transmission was made on July 11, 1962, and was broadcast throughout the United States.

Plans were made for a system of roughly 100 satellites, so that one would always be overhead, but another idea soon proved more practical. In 1945, 12 years before space flight began, the science-fiction writer Arthur C. Clarke proposed placing satellites in orbits 22,300 miles above the earth. A satellite at this altitude orbits with a 24-hour period, so from the ground it appears to hang stationary in space. We now call this a *geosynchronous orbit.* One such satellite would allow microwave communication between two points one-third of a world apart, so just three geosynchronous satellites would span the entire earth.

Much more energy is required to reach geosynchronous orbit than to reach low-earth orbit, but rocket technology was advancing faster than NASA could build Telstar satellites. The first commercial communications satellite was placed in geosynchronous orbit in 1965, and, for the first time, television images could be broadcast live to anywhere in the world. Today all of the world's intercontinental television and much of the intercontinental telephone traffic travel via microwaves to and from a cluster of these artificial stars floating high above the earth.

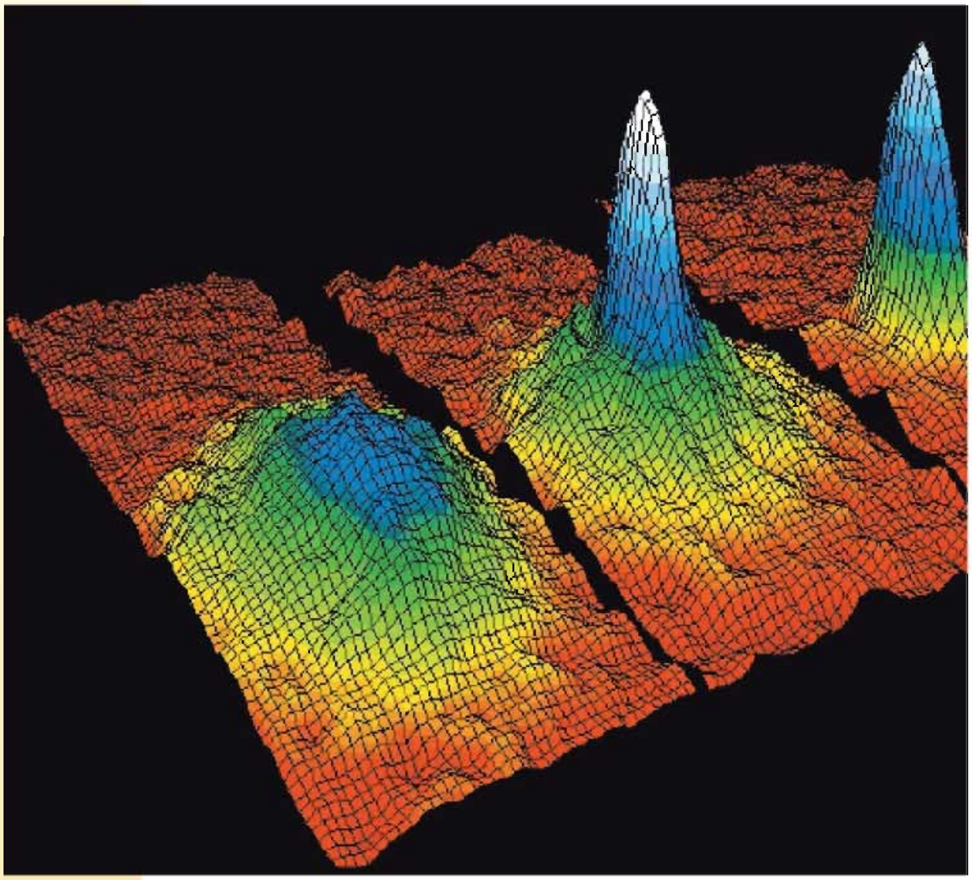
Today, at the beginning of the 21st century, information and images span the world as quickly as or more quickly than they once moved through a small village. You can pick up the phone and talk to friends or relatives anywhere around the globe, and each evening's news brings live images from remote places. Telecommunication unites our world, and the technologies of telecommunications are direct descendants of Coulomb, Ampère, Oersted, Henry, and—most of all—Michael Faraday.



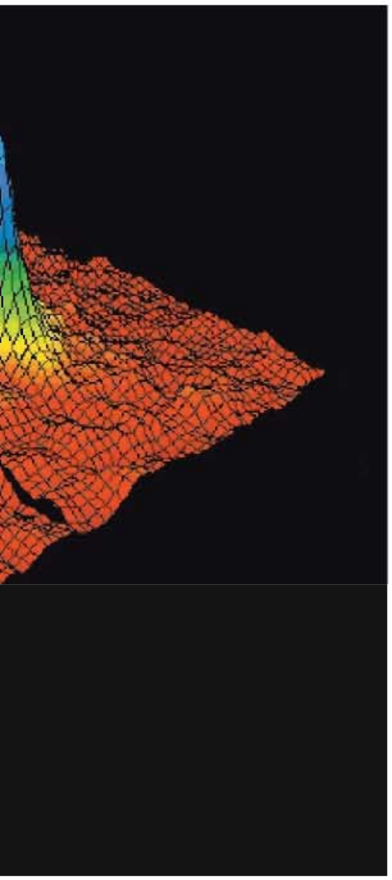
This INTELSAT telecommunications satellite is 12 m (40 ft) long.

PART

VII Relativity and Quantum Physics



This three-frame sequence shows a gas of a few thousand rubidium atoms condensing into a single quantum state known as a Bose-Einstein condensate. This phenomenon was predicted by Einstein in 1925 but not observed until 1995, when physicists learned how to use lasers to cool the atoms to temperatures below 200 nanokelvin.



OVERVIEW

Contemporary Physics

Our journey into physics is nearing its end. We began roughly 350 years ago with Newton's discovery of the laws of motion. Part VI brought us to the end of the 19th century, just over 100 years ago. Along the way you've learned about the motion of particles, the conservation of energy, the physics of waves, and the electromagnetic interactions that hold atoms together and generate light waves. We can begin the last phase of our journey with confidence.

Newton's mechanics and Maxwell's electromagnetism were the twin pillars of science at the end of the 19th century and the basis for much of engineering and applied science in the 20th century. Despite the successes of these theories, a series of discoveries starting around 1900 and continuing into the first few decades of the 20th century profoundly altered our understanding of the universe at the most fundamental level.

- Einstein's theory of relativity forced scientists to completely revise their concepts of space and time. Our exploration of these fascinating ideas will end with perhaps the most famous equation in physics: Einstein's $E = mc^2$.
- Experimenters found that the classical distinction between *particles* and *waves* breaks down at the atomic level. Light sometimes acts like a particle, while electrons and even entire atoms sometimes act like waves. We will need a new theory of light and matter—quantum physics—to explain these phenomena.

These two theories form the basis for physics as it is practiced today, and they are already having a significant impact on 21st-century engineering.

The complete theory of quantum physics, as it was developed in the 1920s, describes atomic particles in terms of an entirely new concept called a *wave function.* One of our most important tasks in Part VII will be to learn what a wave function is, what laws govern its behavior, and how to relate wave functions to experimental measurements. We will concentrate on one-dimensional models that, while not perfect, will be adequate for understanding the essential features of scanning tunneling microscopes, various semiconductor devices, radioactive decay, and other applications.

We'll complete our study of quantum physics with an introduction to atomic and nuclear physics. You will learn where the electron-shell model of chemistry comes from, how atoms emit and absorb light, what's inside the nucleus, and why some nuclei undergo radioactive decay.

The quantum world with its wave functions and probabilities can seem strange and mysterious, yet quantum physics gives the most definitive and accurate predictions of any physical theory ever devised. The contemporary perspective of quantum physics will be a fitting end to our journey into physics.

NOTE ▶ This edition of *Physics for Scientists and Engineers* contains only Chapter 37, Relativity. The complete Part VII may be found in either the hardbound *Physics for Scientists and Engineers with Modern Physics* or in the softbound *Volume 5: Relativity and Quantum Physics.* ◀

37 Relativity

These are the fundamental tools with which we learn about space and time.

Space and time seem like straightforward ideas. You can measure lengths with a ruler or meter stick. You can time events with a stopwatch. Nothing could be simpler.

So it seemed to everyone until 1905, when an unknown young scientist had the nerve to suggest that this simple view of space and time was in conflict with other principles of physics. In the century since, Einstein's theory of relativity has radically altered our understanding of some of the most fundamental ideas in physics.

Relativity, despite its esoteric reputation, has very real implications for modern technology. Global positioning system (GPS) satellites depend on relativity, as do the navigation systems used by airliners. Nuclear reactors make tangible use of Einstein's famous equation $E = mc^2$ to generate 20% of the electricity used in the United States. The annihilation of matter in positron-emission tomography (PET scanners) has given neuroscientists a new ability to monitor activity within the brain.

The theory of relativity is fascinating, perplexing, and challenging. It is also vital to our contemporary understanding of the universe in which we live.

► Looking Ahead

The goal of Chapter 37 is to understand how Einstein's theory of relativity changes our concepts of space and time. In this chapter you will learn to:

- Use the principle of relativity.
- Understand how time dilation and length contraction change our concepts of space and time.
- Use the Lorentz transformations of positions and velocities.
- Calculate relativistic momentum and energy.
- Understand how mass and energy are equivalent.

◄ Looking Back

The material in this chapter depends on an understanding of relative motion in Newtonian mechanics. Please review:

- Section 4.4 Inertial reference frames and the Galilean transformations.

37.1 Relativity: What's It All About?

What do you think of when you hear the phrase "theory of relativity"? A white-haired Einstein? $E = mc^2$? Black holes? Time travel? Perhaps you've heard that the theory of relativity is so complicated and abstract that only a handful of people in the whole world really understand it.

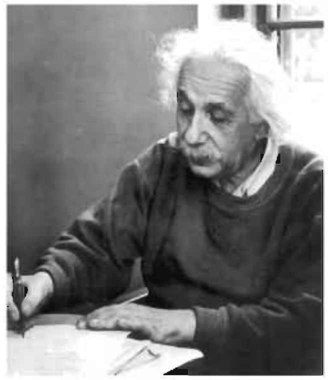
There is, without doubt, a certain mystique associated with relativity, an aura of the strange and exotic. The good news is that understanding the ideas of relativity is well within your grasp. Einstein's *special theory of relativity,* the portion of relativity we'll study, is not mathematically difficult at all. The challenge is conceptual because relativity questions deeply held assumptions about the nature of space and time. In fact, that's what relativity is all about—space and time.

In one sense, relativity is not a new idea at all. Certain ideas about relativity are part of Newtonian mechanics. You had an introduction to these ideas in Chapter 4, where you learned about reference frames and the Galilean transformations. Einstein, however, thought that relativity should apply to *all* the laws of physics, not just mechanics. The difficulty, as you'll see, is that some aspects of relativity appear to be incompati-

ble with the laws of electromagnetism, particularly the laws governing the propagation of light waves.

Lesser scientists might have concluded that relativity simply doesn't apply to electromagnetism. Einstein's genius was to see that the incompatibility arises from *assumptions* about space and time, assumptions no one had ever questioned because they seem so obviously true. Rather than abandon the ideas of relativity, Einstein changed our understanding of space and time.

Fortunately, you need not be a genius to follow a path that someone else has blazed. However, we will have to exercise the utmost care with regard to logic and precision. We will need to state very precisely just how it is that we know things about the physical world, then ruthlessly follow the logical consequences. The challenge is to stay on this path, not to let our prior assumptions—assumptions that are deeply ingrained in all of us—lead us astray.



Albert Einstein (1879–1955) was one of the most influential thinkers in history.

What's Special About Special Relativity?

Einstein's first paper on relativity, in 1905, dealt exclusively with inertial reference frames, reference frames that move relative to each other with constant velocity. Ten years later, Einstein published a more encompassing theory of relativity that considered accelerated motion and its connection to gravity. The second theory, because it's more general in scope, is called *general relativity*. General relativity is the theory that describes black holes, curved spacetime, and the evolution of the universe. It is a fascinating theory but, alas, very mathematical and outside the scope of this textbook.

Motion at constant velocity is a "special case" of motion—namely, motion for which the acceleration is zero. Hence Einstein's first theory of relativity has come to be known as **special relativity.** It is special in the sense of being a restricted, special case of his more general theory, not special in the everyday sense meaning distinctive or exceptional. Special relativity, with its conclusions about time dilation and length contraction, is what we will study.

37.2 Galilean Relativity

A firm grasp of Galilean relativity is necessary if we are to appreciate and understand what is new in Einstein's theory. Thus we begin with the ideas of relativity that are embodied in Newtonian mechanics.

Reference Frames

Suppose you're passing me as we both drive in the same direction along a freeway. My car's speedometer reads 55 mph while your speedometer shows 60 mph. Is 60 mph your "true" speed? That is certainly your speed relative to someone standing beside the road, but your speed relative to me is only 5 mph. Your speed is 120 mph relative to a driver approaching from the other direction at 60 mph.

An object does not have a "true" speed or velocity. The very definition of velocity, $v = \Delta x/\Delta t$, assumes the existence of a coordinate system in which, during some time interval Δt, the displacement Δx is measured. The best we can manage is to specify an object's velocity relative to, or with respect to, the coordinate system in which it is measured.

Let's define a **reference frame** to be a coordinate system in which experimenters equipped with meter sticks, stopwatches, and any other needed equipment make position and time measurements on moving objects. Three ideas are implicit in our definition of a reference frame:

- A reference frame extends infinitely far in all directions.
- The experimenters are at rest in the reference frame.
- The number of experimenters and the quality of their equipment are sufficient to measure positions and velocities to any level of accuracy needed.

The first two ideas are especially important. It is often convenient to say "the laboratory reference frame" or "the reference frame of the rocket." These are shorthand expressions for "a reference frame, infinite in all directions, in which the laboratory (or the rocket) and a set of experimenters happen to be at rest."

NOTE ▶ A reference frame is not the same thing as a "point of view." That is, each person or each experimenter does not have his or her own private reference frame. **All experimenters at rest relative to each other share the same reference frame.** ◀

FIGURE 37.1 The standard reference frames S and S′.

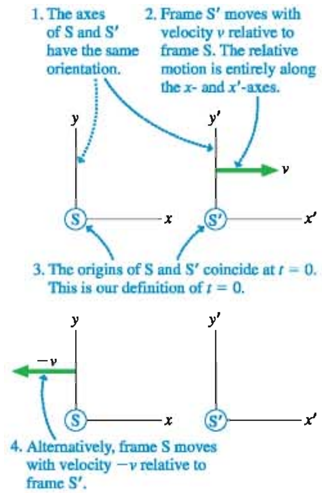


FIGURE 37.1 shows two reference frames called S and S′. The coordinate axes in S are x, y, z and those in S′ are x', y', z'. Reference frame S′ moves with velocity v relative to S or, equivalently, S moves with velocity $-v$ relative to S′. There's no implication that either reference frame is "at rest." Notice that the zero of time, when experimenters start their stopwatches, is the instant that the origins of S and S′ coincide.

We will restrict our attention to *inertial reference frames,* implying that the relative velocity v is constant. You should recall from Chapter 5 that an **inertial reference frame** is a reference frame in which Newton's first law, the law of inertia, is valid. In particular, an inertial reference frame is one in which an isolated particle, one on which there are no forces, either remains at rest or moves in a straight line at constant speed.

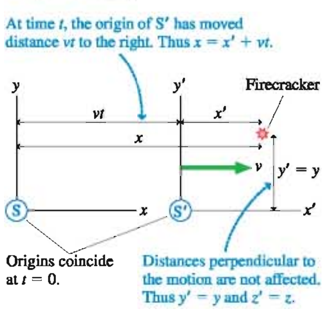
Any reference frame moving at constant velocity with respect to an inertial reference frame is itself an inertial reference frame. Conversely, a reference frame accelerating with respect to an inertial reference frame is *not* an inertial reference frame. Our restriction to reference frames moving with respect to each other at constant velocity—with no acceleration—is the "special" part of special relativity.

NOTE ▶ An inertial reference frame is an idealization. A true inertial reference frame would need to be floating in deep space, far from any gravitational influence. In practice, an earthbound laboratory is a good approximation of an inertial reference frame because the accelerations associated with the earth's rotation and motion around the sun are too small to influence most experiments. ◀

STOP TO THINK 37.1 Which of these is an inertial reference frame (or a very good approximation)?

a. Your bedroom
b. A car rolling down a steep hill
c. A train coasting along a level track
d. A rocket being launched
e. A roller coaster going over the top of a hill
f. A sky diver falling at terminal speed

FIGURE 37.2 The position of an exploding firecracker is measured in reference frames S and S′.



The Galilean Transformations

Suppose a firecracker explodes at time t. The experimenters in reference frame S determine that the explosion happened at position x. Similarly, the experimenters in S′ find that the firecracker exploded at x' in their reference frame. What is the relationship between x and x'?

FIGURE 37.2 shows the explosion and the two reference frames. You can see from the figure that $x = x' + vt$, thus

$$\begin{aligned} x &= x' + vt \\ y &= y' \\ z &= z' \end{aligned} \qquad \text{or} \qquad \begin{aligned} x' &= x - vt \\ y' &= y \\ z' &= z \end{aligned} \tag{37.1}$$

These equations, which you saw in Chapter 4, are the *Galilean transformations of position.* If you know a position measured by the experimenters in one inertial reference frame, you can calculate the position that would be measured by experimenters in any other inertial reference frame.

Suppose the experimenters in both reference frames now track the motion of the object in FIGURE 37.3 by measuring its position at many instants of time. The experimenters in S find that the object's velocity is $\vec{u}$. During the *same time interval* Δt, the experimenters in S′ measure the velocity to be $\vec{u}'$.

NOTE ▶ In this chapter, we will use v to represent the velocity of one reference frame relative to another. We will use $\vec{u}$ and $\vec{u}'$ to represent the velocities of objects with respect to reference frames S and S′. This notation differs from the notation of Chapter 4, where we used V to represent the relative velocity. ◀

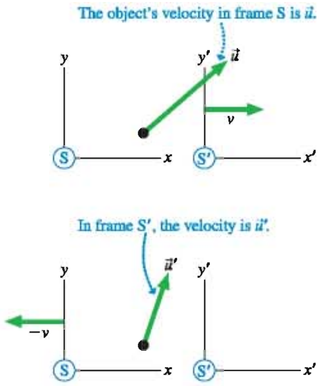


FIGURE 37.3 The velocity of a moving object is measured in reference frames S and S′.

We can find the relationship between $\vec{u}$ and $\vec{u}'$ by taking the time derivatives of Equation 37.1 and using the definition $u_x = dx/dt$:

$$u_x = \frac{dx}{dt} = \frac{dx'}{dt} + v = u_x' + v$$

$$u_y = \frac{dy}{dt} = \frac{dy'}{dt} = u_y'$$

The equation for u_z is similar. The net result is

$$\begin{aligned} u_x &= u_x' + v \\ u_y &= u_y' \\ u_z &= u_z' \end{aligned} \qquad \text{or} \qquad \begin{aligned} u_x' &= u_x - v \\ u_y' &= u_y \\ u_z' &= u_z \end{aligned} \tag{37.2}$$

Equations 37.2 are the *Galilean transformations of velocity.* If you know the velocity of a particle as measured by the experimenters in one inertial reference frame, you can use Equations 37.2 to find the velocity that would be measured by experimenters in any other inertial reference frame.

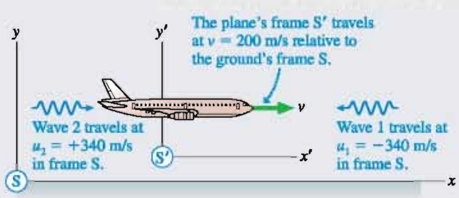
EXAMPLE 37.1 The speed of sound

An airplane is flying at speed 200 m/s with respect to the ground. Sound wave 1 is approaching the plane from the front, sound wave 2 is catching up from behind. Both waves travel at 340 m/s relative to the ground. What is the speed of each wave relative to the plane?

MODEL Assume that the earth (frame S) and the airplane (frame S′) are inertial reference frames. Frame S′, in which the airplane is at rest, moves at $v = 200$ m/s relative to frame S.

VISUALIZE FIGURE 37.4 shows the airplane and the sound waves.

FIGURE 37.4 Experimenters in the plane measure different speeds for the waves than do experimenters on the ground.



SOLVE The speed of a mechanical wave, such as a sound wave or a wave on a string, is its speed *relative to its medium.* Thus the *speed of sound* is the speed of a sound wave through a reference frame in which the air is at rest. This is reference frame S, where wave 1 travels with velocity $u_1 = -340$ m/s and wave 2 travels with velocity $u_2 = +340$ m/s. Notice that the Galilean transformations use *velocities*, with appropriate signs, not just speeds.

The airplane travels to the right with reference frame S′ at velocity v. We can use the Galilean transformations of velocity to find the velocities of the two sound waves in frame S′:

$$u_1' = u_1 - v = -340 \text{ m/s} - 200 \text{ m/s} = -540 \text{ m/s}$$

$$u_2' = u_2 - v = 340 \text{ m/s} - 200 \text{ m/s} = 140 \text{ m/s}$$

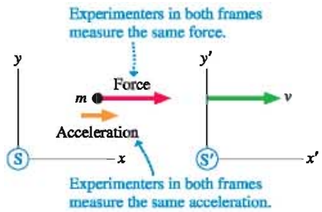
ASSESS This isn't surprising. If you're driving at 50 mph, a car coming the other way at 55 mph is approaching you at 105 mph. A car coming up behind you at 55 mph seems to be gaining on you at the rate of only 5 mph. Wave speeds behave the same. Notice that a mechanical wave would appear to be stationary to a person moving at the wave speed. To a surfer, the crest of the ocean wave remains at rest under his or her feet.

STOP TO THINK 37.2 Ocean waves are approaching the beach at 10 m/s. A boat heading out to sea travels at 6 m/s. How fast are the waves moving in the boat's reference frame?

a. 16 m/s b. 10 m/s c. 6 m/s d. 4 m/s

The Galilean Principle of Relativity

FIGURE 37.5 Experimenters in both reference frames test Newton's second law by measuring the force on a particle and its acceleration.



Experimenters in reference frames S and S′ measure different values for position and velocity. What about the force on and the acceleration of the particle in FIGURE 37.5? The strength of a force can be measured with a spring scale. The experimenters in reference frames S and S′ both see the *same reading* on the scale (assume the scale has a bright digital display easily seen by all experimenters), so both conclude that the force is the same. That is, $F' = F$.

We can compare the accelerations measured in the two reference frames by taking the time derivative of the velocity transformation equation $u' = u - v$. (We'll assume, for simplicity, that the velocities and accelerations are all in the x-direction.) The relative velocity v between the two reference frames is *constant,* with $dv/dt = 0$, thus

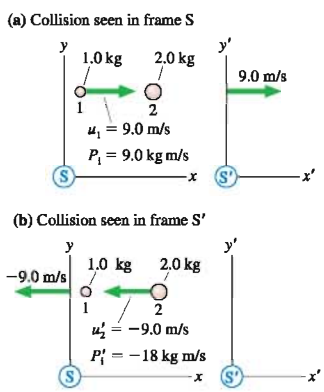
$$a' = \frac{du'}{dt} = \frac{du}{dt} = a \tag{37.3}$$

Experimenters in reference frames S and S′ measure different values for an object's position and velocity, but they *agree* on its acceleration.

If $F = ma$ in reference frame S, then $F' = ma'$ in reference frame S′. Stated another way, if Newton's second law is valid in one inertial reference frame, then it is valid in all inertial reference frames. Because other laws of mechanics, such as the conservation laws, follow from Newton's laws of motion, we can state this conclusion as the *Galilean principle of relativity:*

Galilean principle of relativity The laws of mechanics are the same in all inertial reference frames.

FIGURE 37.6 Total momentum measured in two reference frames.



The Galilean principle of relativity is easy to state, but to understand it we must understand what is and is not "the same." To take a specific example, consider the law of conservation of momentum. FIGURE 37.6a shows two particles about to collide. Their total momentum in frame S, where particle 2 is at rest, is $P_i = 9.0$ kgm/s. This is an isolated system, hence the law of conservation of momentum tells us that the momentum after the collision will be $P_f = 9.0$ kgm/s.

FIGURE 37.6b has used the velocity transformation to look at the same particles in frame S′ in which particle 1 is at rest. The initial momentum in S′ is $P_i' = -18$ kgm/s. Thus it is not the *value* of the momentum that is the same in all inertial reference frames. Instead, the Galilean principle of relativity tells us that the *law* of momentum conservation is the same in all inertial reference frames. If $P_f = P_i$ in frame S, then it must be true that $P_f' = P_i'$ in frame S′. Consequently, we can conclude that P_f' will be -18 kgm/s after the collision in S′.

Using Galilean Relativity

The principle of relativity is concerned with the laws of mechanics, not with the values that are needed to satisfy the laws. If momentum is conserved in one inertial reference frame, it is conserved in all inertial reference frames. Even so, a problem may be easier to solve in one reference frame than in others.

Elastic collisions provide a good example of using reference frames. You learned in Chapter 10 how to calculate the outcome of a perfectly elastic collision between two particles in the reference frame in which particle 2 is initially at rest. We can use that information together with the Galilean transformations to solve elastic-collision problems in any inertial reference frame.

TACTICS BOX 37.1 Analyzing elastic collisions

MP

1. Transform the initial velocities of particles 1 and 2 from frame S to reference frame S′ in which particle 2 is at rest.
2. The outcome of the collision in S′ is given by

$$u'_{1f} = \frac{m_1 - m_2}{m_1 + m_2}u'_{1i}$$

$$u'_{2f} = \frac{2m_1}{m_1 + m_2}u'_{1i}$$

3. Transform the two final velocities from frame S′ back to frame S.

Exercises 4–5

EXAMPLE 37.2 An elastic collision

A 300 g ball moving to the right at 2.0 m/s has a perfectly elastic collision with a 100 g ball moving to the left at 4.0 m/s. What are the direction and speed of each ball after the collision?

MODEL The velocities are measured in the laboratory frame, which we call frame S.

VISUALIZE FIGURE 37.7a shows both the balls and a reference frame S′ in which ball 2 is at rest.

SOLVE The three steps of Tactics Box 37.1 are illustrated in FIGURE 37.7b. We're given u_{1i} and u_{2i}. The Galilean transformations of these velocities to frame S′, using $v = -4.0$ m/s, are

$$u'_{1i} = u_{1i} - v = (2.0\text{ m/s}) - (-4.0\text{ m/s}) = 6.0\text{ m/s}$$

$$u'_{2i} = u_{2i} - v = (-4.0\text{ m/s}) - (-4.0\text{ m/s}) = 0\text{ m/s}$$

The 100 g ball is at rest in frame S′, which is what we wanted. The velocities after the collision are

$$u'_{1f} = \frac{m_1 - m_2}{m_1 + m_2}u'_{1i} = 3.0\text{ m/s}$$

$$u'_{2f} = \frac{2m_1}{m_1 + m_2}u'_{1i} = 9.0\text{ m/s}$$

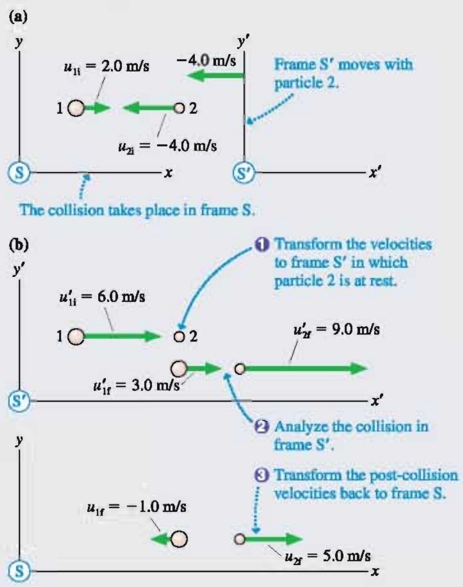
We've finished the collision analysis, but we're not done because these are the post-collision velocities in frame S′. Another application of the Galilean transformations tells us that the post-collision velocities in frame S are

$$u_{1f} = u'_{1f} + v = (3.0\text{ m/s}) + (-4.0\text{ m/s}) = -1.0\text{ m/s}$$

$$u_{2f} = u'_{2f} + v = (9.0\text{ m/s}) + (-4.0\text{ m/s}) = 5.0\text{ m/s}$$

Thus the 300 g ball rebounds to the left at a speed of 1.0 m/s and the 100 g ball is knocked to the right at a speed of 5.0 m/s.

FIGURE 37.7 Using reference frames to solve an elastic-collision problem.



ASSESS You can easily verify that momentum is conserved: $P_f = P_i = 0.20$ kgm/s. The calculations in this example were easy. The important point of this example, and one worth careful thought, is the *logic* of what we did and why we did it.

37.3 Einstein's Principle of Relativity

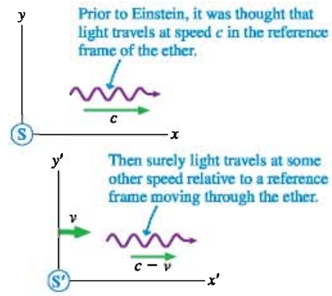
The 19th century was an era of optics and electromagnetism. Thomas Young demonstrated in 1801 that light is a wave, and by midcentury scientists had devised techniques for measuring the speed of light. Faraday discovered electromagnetic induction in 1831, setting in motion a train of events leading to Maxwell's conclusion, in 1864, that light is an electromagnetic wave.

If light is a wave, what is the medium in which it travels? This was perhaps *the* most important scientific question of the second half of the 19th century. The medium in which light waves were assumed to travel was called the **ether**. Experiments to measure the speed of light were assumed to be measuring its speed through the ether. But just what *is* the ether? What are its properties? Can we collect a jar full of ether to study? Despite the significance of these questions, efforts to detect the ether or measure its properties kept coming up empty handed.

Maxwell's theory of electromagnetism didn't help the situation. The crowning success of Maxwell's theory was his prediction that light waves travel with speed

$$c = \frac{1}{\sqrt{\epsilon_0 \mu_0}} = 3.00 \times 10^8 \text{ m/s}$$

FIGURE 37.8 It seems as if the speed of light should differ from c in a reference frame moving through the ether.



This is a very specific prediction with no wiggle room. The difficulty with such a specific prediction was the implication that Maxwell's laws of electromagnetism are valid *only* in the reference frame of the ether. After all, as FIGURE 37.8 shows, the light speed should certainly be larger or smaller than c in a reference frame moving through the ether, just as the sound speed is different to someone moving through the air.

As the 19th century closed, it appeared that Maxwell's theory did not obey the classical principle of relativity. There was just one reference frame, the reference frame of the ether, in which the laws of electromagnetism seemed to be true. And to make matters worse, the fact that no one had been able to detect the ether meant that no one could identify the one reference frame in which Maxwell's equations "worked."

It was in this muddled state of affairs that a young Albert Einstein made his mark on the world. Even as a teenager, Einstein had wondered how a light wave would look to someone "surfing" the wave, traveling alongside the wave at the wave speed. You can do that with a water wave or a sound wave, but light waves seemed to present a logical difficulty. An electromagnetic wave sustains itself by virtue of the fact that a changing magnetic field induces an electric field and a changing electric field induces a magnetic field. But to someone moving with the wave, *the fields would not change.* How could there be an electromagnetic wave under these circumstances?

Several years of thinking about the connection between electromagnetism and reference frames led Einstein to the conclusion that *all* the laws of physics, not just the laws of mechanics, should obey the principle of relativity. In other words, the principle of relativity is a fundamental statement about the nature of the physical universe. Thus we can remove the restriction in the Galilean principle of relativity and state a much more general principle:

Principle of relativity All the laws of physics are the same in all inertial reference frames.

All the results of Einstein's theory of relativity flow from this one simple statement.

The Constancy of the Speed of Light

If Maxwell's equations of electromagnetism are laws of physics, and there's every reason to think they are, then, according to the principle of relativity, Maxwell's equations must be true in *every* inertial reference frame. On the surface this seems to be an

innocuous statement, equivalent to saying that the law of conservation of momentum is true in every inertial reference frame. But follow the logic:

1. Maxwell's equations are true in all inertial reference frames.
2. Maxwell's equations predict that electromagnetic waves, including light, travel at speed $c = 3.00 \times 10^8$ m/s.
3. Therefore, **light travels at speed c in all inertial reference frames.**

FIGURE 37.9 shows the implications of this conclusion. *All* experimenters, regardless of how they move with respect to each other, find that *all* light waves, regardless of the source, travel in their reference frame with the *same* speed c. If Cathy's velocity toward Bill and away from Amy is $v = 0.9c$, Cathy finds, by making measurements in her reference frame, that the light from Bill approaches her at speed c, not at $c + v = 1.9c$. And the light from Amy, which left Amy at speed c, catches up from behind at speed c *relative to Cathy,* not the $c - v = 0.1c$ you would have expected.

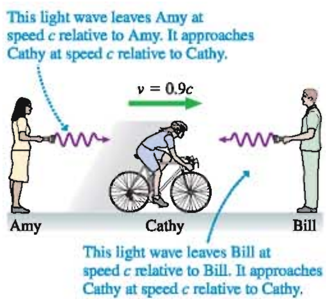


FIGURE 37.9 Light travels at speed c in all inertial reference frames, regardless of how the reference frames are moving with respect to the light source.

Although this prediction goes against all shreds of common sense, the experimental evidence for it is strong. Laboratory experiments are difficult because even the highest laboratory speed is insignificant in comparison to c. In the 1930s, however, physicists R. J. Kennedy and E. M. Thorndike realized that they could use the earth itself as a laboratory. The earth's speed as it circles the sun is about 30,000 m/s. The *relative* velocity of the earth in January differs by 60,000 m/s from its velocity in July, when the earth is moving in the opposite direction. Kennedy and Thorndike were able to use a very sensitive and stable interferometer to show that the numerical values of the speed of light in January and July differ by less than 2 m/s.

More recent experiments have used unstable elementary particles, called π mesons, that decay into high-energy photons of light. The π mesons, created in a particle accelerator, move through the laboratory at 99.975% the speed of light, or $v = 0.99975c$, as they emit photons at speed c in the π meson's reference frame. As FIGURE 37.10 shows, you would expect the photons to travel through the laboratory with speed $c + v = 1.99975c$. Instead, the measured speed of the photons in the laboratory was, within experimental error, 3.00×10^8 m/s.

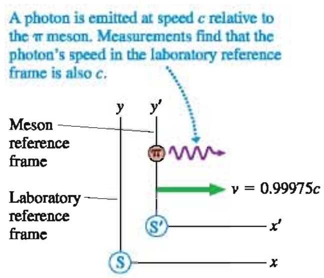

FIGURE 37.10 Experiments find that the photons travel through the laboratory with speed c, not the speed $1.99975c$ that you might expect.

In summary, *every* experiment designed to compare the speed of light in different reference frames has found that light travels at 3.00×10^8 m/s in every inertial reference frame, regardless of how the reference frames are moving with respect to each other.

How Can This Be?

You're in good company if you find this impossible to believe. Suppose I shot a ball forward at 50 m/s while driving past you at 30 m/s. You would certainly see the ball traveling at 80 m/s relative to you and the ground. What we're saying with regard to light is equivalent to saying that the ball travels at 50 m/s relative to my car and *at the same time* travels at 50 m/s relative to the ground, even though the car is moving across the ground at 30 m/s. It seems logically impossible.

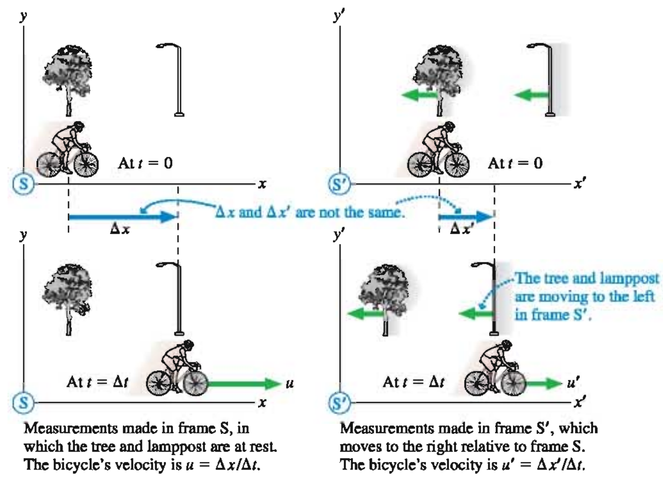
You might think that this is merely a matter of semantics. If we can just get our definitions and use of words straight, then the mystery and confusion will disappear. Or perhaps the difficulty is a confusion between what we "see" versus what "really happens." In other words, a better analysis, one that focuses on what really happens, would find that light "really" travels at different speeds in different reference frames.

Alas, what "really happens" is that light travels at 3.00×10^8 m/s in every inertial reference frame, regardless of how the reference frames are moving with respect to each other. It's not a trick. There remains only one way to escape the logical contradictions.

The definition of velocity is $u = \Delta x/\Delta t$, the ratio of a distance traveled to the time interval in which the travel occurs. Suppose you and I both make measurements on an

object as it moves, but you happen to be moving relative to me. Perhaps I'm standing on the corner, you're driving past in your car, and we're both trying to measure the velocity of a bicycle. Further, suppose we have agreed in advance to measure the bicycle as it moves from the tree to the lamppost in FIGURE 37.11. Your $\Delta x'$ differs from my Δx because of your motion relative to me, causing you to calculate a bicycle velocity u' in your reference frame that differs from its velocity u in my reference frame. This is just the Galilean transformations showing up again.

FIGURE 37.11 Measuring the velocity of an object by appealing to the basic definition $u = \Delta x/\Delta t$.



Now let's repeat the measurements, but this time let's measure the velocity of a light wave as it travels from the tree to the lamppost. Once again, your $\Delta x'$ differs from my Δx, although the difference will be pretty small unless your car is moving at well above the legal speed limit. The obvious conclusion is that your light speed u' differs from my light speed u. But it doesn't. The experiments show that, for a light wave, we'll get the *same* values: $u' = u$.

The only way this can be true is if your Δt is not the same as my Δt. If the time it takes the light to move from the tree to the lamppost in your reference frame, a time we'll now call $\Delta t'$, differs from the time Δt it takes the light to move from the tree to the lamppost in my reference frame, then we might find that $\Delta x'/\Delta t' = \Delta x/\Delta t$. That is, $u' = u$ even though you are moving with respect to me.

We've assumed, since the beginning of this textbook, that time is simply time. It flows along like a river, and all experimenters in all reference frames simply use it. For example, suppose the tree and the lamppost both have big clocks that we both can see. Shouldn't we be able to agree on the time interval Δt the light needs to move from the tree to the lamppost?

Perhaps not. It's demonstrably true that $\Delta x' \neq \Delta x$. It's experimentally verified that $u' = u$ for light waves. Something must be wrong with *assumptions* that we've made about the nature of time. The principle of relativity has painted us into a corner, and our only way out is to reexamine our understanding of time.

37.4 Events and Measurements

To question some of our most basic assumptions about space and time requires extreme care. We need to be certain that no assumptions slip into our analysis unnoticed. Our goal is to describe the motion of a particle in a clear and precise way, making the barest minimum of assumptions.

Events

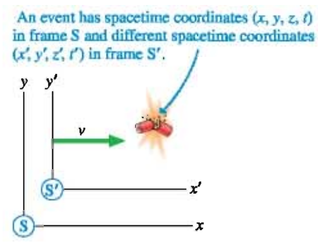
The fundamental entity of relativity is called an **event.** An event is a physical activity that takes place at a definite point in space and at a definite instant of time. An exploding firecracker is an event. A collision between two particles is an event. A light wave hitting a detector is an event.

Events can be observed and measured by experimenters in different reference frames. An exploding firecracker is as clear to you as you drive by in your car as it is to me standing on the street corner. We can quantify where and when an event occurs with four numbers: the coordinates (x, y, z) and the instant of time t. These four numbers, illustrated in FIGURE 37.12, are called the **spacetime coordinates** of the event.

The spatial coordinates of an event measured in reference frames S and S′ may differ. It now appears that the instant of time recorded in S and S′ may also differ. Thus the spacetime coordinates of an event measured by experimenters in frame S are (x, y, z, t) and the spacetime coordinates of the *same event* measured by experimenters in frame S′ are (x', y', z', t').

The motion of a particle can be described as a sequence of two or more events. We introduced this idea in the preceding section when we agreed to measure the velocity of a bicycle and then of a light wave by comparing the object passing the tree (first event) to the object passing the lamppost (second event).

FIGURE 37.12 The location and time of an event are described by its spacetime coordinates.



Measurements

Events are what "really happen," but how do we learn about an event? That is, how do the experimenters in a reference frame determine the spacetime coordinates of an event? This is a problem of *measurement.*

We defined a reference frame to be a coordinate system in which experimenters can make position and time measurements. That's a good start, but now we need to be more precise as to *how* the measurements are made. Imagine that a reference frame is filled with a cubic lattice of meter sticks, as shown in FIGURE 37.13. At every intersection is a clock, and all the clocks in a reference frame are *synchronized.* We'll return in a moment to consider how to synchronize the clocks, but assume for the moment it can be done.

Now, with our meter sticks and clocks in place, we can use a two-part measurement scheme:

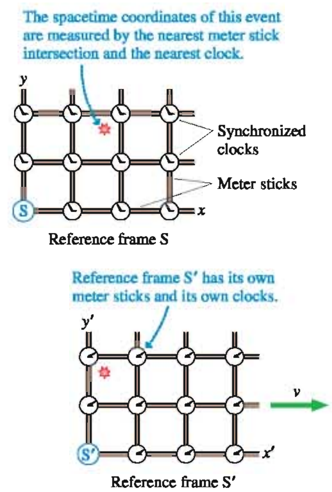
- The (x, y, z) coordinates of an event are determined by the intersection of the meter sticks closest to the event.
- The event's time t is the time displayed on the clock nearest the event.

You can imagine, if you wish, that each event is accompanied by a flash of light to illuminate the face of the nearest clock and make its reading known.

Several important issues need to be noted:

1. The clocks and meter sticks in each reference frame are imaginary, so they have no difficulty passing through each other.
2. Measurements of position and time made in one reference frame must use only the clocks and meter sticks in that reference frame.
3. There's nothing special about the sticks being 1 m long and the clocks 1 m apart. The lattice spacing can be altered to achieve whatever level of measurement accuracy is desired.

FIGURE 37.13 The spacetime coordinates of an event are measured by a lattice of meter sticks and clocks.



4. We'll assume that the experimenters in each reference frame have assistants sitting beside every clock to record the position and time of nearby events.
5. Perhaps most important, t is the time at which the event *actually happens,* not the time at which an experimenter sees the event or at which information about the event reaches an experimenter.
6. All experimenters in one reference frame agree on the spacetime coordinates of an event. In other words, **an event has a unique set of spacetime coordinates in each reference frame.**

STOP TO THINK 37.3 A carpenter is working on a house two blocks away. You notice a slight delay between seeing the carpenter's hammer hit the nail and hearing the blow. At what time does the event "hammer hits nail" occur?

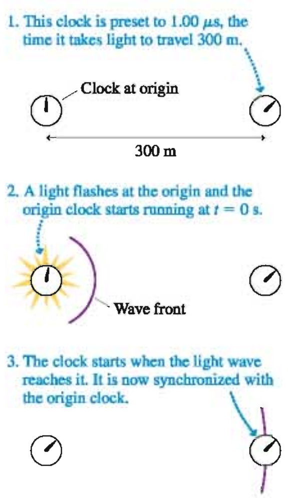
a. At the instant you hear the blow
b. At the instant you see the hammer hit
c. Very slightly before you see the hammer hit
d. Very slightly after you see the hammer hit

Clock Synchronization

It's important that all the clocks in a reference frame be **synchronized,** meaning that all clocks in the reference frame have the same reading at any one instant of time. Thus we need a method of synchronization. One idea that comes to mind is to designate the clock at the origin as the *master clock.* We could then carry this clock around to every clock in the lattice, adjust that clock to match the master clock, and finally return the master clock to the origin.

This would be a perfectly good method of clock synchronization in Newtonian mechanics, where time flows along smoothly, the same for everyone. But we've been driven to reexamine the nature of time by the possibility that time is different in reference frames moving relative to each other. Because the master clock would *move,* we cannot assume that the moving master clock would keep time in the same way as the stationary clocks.

FIGURE 37.14 Synchronizing clocks.



We need a synchronization method that does not require moving the clocks. Fortunately, such a method is easy to devise. Each clock is resting at the intersection of meter sticks, so by looking at the meter sticks, the assistant knows, or can calculate, exactly how far each clock is from the origin. Once the distance is known, the assistant can calculate exactly how long a light wave will take to travel from the origin to each clock. For example, light will take 1.00 μs to travel to a clock 300 m from the origin.

NOTE ▶ It's handy for many relativity problems to know that the speed of light is $c = 300\ \text{m}/\mu\text{s}$. ◀

To synchronize the clocks, the assistants begin by setting each clock to display the light travel time from the origin, but they don't start the clocks. Next, as FIGURE 37.14 shows, a light flashes at the origin and, simultaneously, the clock at the origin starts running from $t = 0$ s. The light wave spreads out in all directions at speed c. A photodetector on each clock recognizes the arrival of the light wave and, without delay, starts the clock. The clock had been preset with the light travel time, so each clock as it starts reads exactly the same as the clock at the origin. Thus all the clocks will be synchronized after the light wave has passed by.

Events and Observations

We noted above that t is the time the event *actually happens*. This is an important point, one that bears further discussion. Light waves take time to travel. Messages, whether they're transmitted by light pulses, telephone, or courier on horseback, take time to be delivered. An experimenter *observes* an event, such as an exploding firecracker, only *at a later time* when light waves reach his or her eyes. But our interest is in the event itself, not the experimenter's observation of the event. The time at which the experimenter sees the event or receives information about the event is not when the event actually occurred.

Suppose at $t = 0$ s a firecracker explodes at $x = 300$ m. The flash of light from the firecracker will reach an experimenter at the origin at $t_1 = 1.0\ \mu s$. The sound of the explosion will reach a sightless experimenter at $t_2 = 0.88$ s. Neither of these is the time t_{event} of the explosion, although the experimenter can work backward from these times, using known wave speeds, to determine t_{event}. In this example, the spacetime coordinates of the event—the explosion—are (300 m, 0 m, 0 m, 0 s).

EXAMPLE 37.3 Finding the time of an event

Experimenter A in reference frame S stands at the origin looking in the positive x-direction. Experimenter B stands at $x = 900$ m looking in the negative x-direction. A firecracker explodes somewhere between them. Experimenter B sees the light flash at $t = 3.0\ \mu s$. Experimenter A sees the light flash at $t = 4.0\ \mu s$. What are the spacetime coordinates of the explosion?

MODEL Experimenters A and B are in the same reference frame and have synchronized clocks.

VISUALIZE FIGURE 37.15 shows the two experimenters and the explosion at unknown position x.

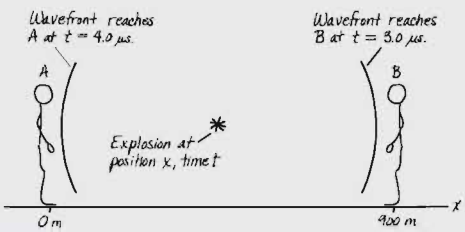


FIGURE 37.15 The light wave reaches the experimenters at different times. Neither of these is the time at which the event actually happened.

SOLVE The two experimenters observe light flashes at two different instants, but there's only one event. Light travels 300 m/μs, so the additional 1.0 μs needed for the light to reach experimenter A implies that distance $(x - 0\text{ m})$ is 300 m longer than distance $(900\text{ m} - x)$. That is,

$$(x - 0\text{ m}) = (900\text{ m} - x) + 300\text{ m}$$

This is easily solved to give $x = 600$ m as the position coordinate of the explosion. The light takes 1.0 μs to travel 300 m to experimenter B, 2.0 μs to travel 600 m to experimenter A. The light is received at 3.0 μs and 4.0 μs, respectively; hence it was emitted by the explosion at $t = 2.0\ \mu s$. The spacetime coordinates of the explosion are (600 m, 0 m, 0 m, 2.0 μs).

ASSESS Although the experimenters *see* the explosion at different times, they agree that the explosion actually *happened* at $t = 2.0\ \mu s$.

Simultaneity

Two events 1 and 2 that take place at different positions x_1 and x_2 but at the *same time* $t_1 = t_2$, as measured in some reference frame, are said to be **simultaneous** in that reference frame. Simultaneity is determined by when the events actually happen, not when they are seen or observed. In general, simultaneous events are *not* seen at the same time because of the difference in light travel times from the events to an experimenter.

EXAMPLE 37.4 Are the explosions simultaneous?

An experimenter in reference frame S stands at the origin looking in the positive x-direction. At $t = 3.0\ \mu s$ she sees firecracker 1 explode at $x = 600$ m. A short time later, at $t = 5.0\ \mu s$, she sees firecracker 2 explode at $x = 1200$ m. Are the two explosions simultaneous? If not, which firecracker exploded first?

MODEL Light from both explosions travels toward the experimenter at 300 m/μs.

SOLVE The experimenter *sees* two different explosions, but perceptions of the events are not the events themselves. When did the explosions *actually* occur? Using the fact that light travels at 300 m/μs, we can see that firecracker 1 exploded at $t_1 = 1.0\ \mu s$ and firecracker 2 also exploded at $t_2 = 1.0\ \mu s$. The events *are* simultaneous.

STOP TO THINK 37.4 A tree and a pole are 3000 m apart. Each is suddenly hit by a bolt of lightning. Mark, who is standing at rest midway between the two, sees the two lightning bolts at the same instant of time. Nancy is at rest under the tree. Define event 1 to be "lightning strikes tree" and event 2 to be "lightning strikes pole." For Nancy, does event 1 occur before, after, or at the same time as event 2?

37.5 The Relativity of Simultaneity

We've now established a means for measuring the time of an event in a reference frame, so let's begin to investigate the nature of time. The following "thought experiment" is very similar to one suggested by Einstein.

FIGURE 37.16 A railroad car traveling to the right with velocity v.

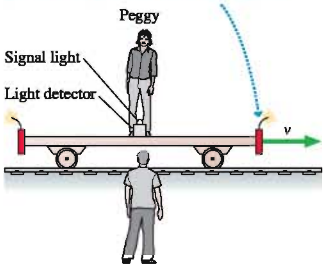

FIGURE 37.16 shows a long railroad car traveling to the right with a velocity v that may be an appreciable fraction of the speed of light. A firecracker is tied to each end of the car, right above the ground. Each firecracker is powerful enough so that, when it explodes, it will make a burn mark on the ground at the position of the explosion.

Ryan is standing on the ground, watching the railroad car go by. Peggy is standing in the exact center of the car with a special box at her feet. This box has two light detectors, one facing each way, and a signal light on top. The box works as follows:

1. If a flash of light is received at the right detector before a flash is received at the left detector, then the light on top of the box will turn green.
2. If a flash of light is received at the left detector before a flash is received at the right detector, or if two flashes arrive simultaneously, the light on top will turn red.

The firecrackers explode as the railroad car passes Ryan, and he sees the two light flashes from the explosions simultaneously. He then measures the distances to the two burn marks and finds that he was standing exactly halfway between the marks. Because light travels equal distances in equal times, Ryan concludes that the two explosions were simultaneous in his reference frame, the reference frame of the ground. Further, because he was midway between the two ends of the car, he was directly opposite Peggy when the explosions occurred.

FIGURE 37.17a shows the sequence of events in Ryan's reference frame. Light travels at speed c in all inertial reference frames, so, although the firecrackers were moving, the light waves are spheres centered on the burn marks. Ryan determines that the light wave coming from the right reaches Peggy and the box before the light wave coming from the left. Thus, according to Ryan, the signal light on top of the box turns green.

How do things look in Peggy's reference frame, a reference frame moving to the right at velocity v relative to the ground? As FIGURE 37.17b shows, Peggy sees Ryan moving to the left with speed v. Light travels at speed c in all inertial reference frames, so the light waves are spheres centered on the ends of the car. If the explosions are simultaneous, as Ryan has determined, the two light waves reach her and the box simultaneously. Thus, according to Peggy, the signal light on top of the box turns red!

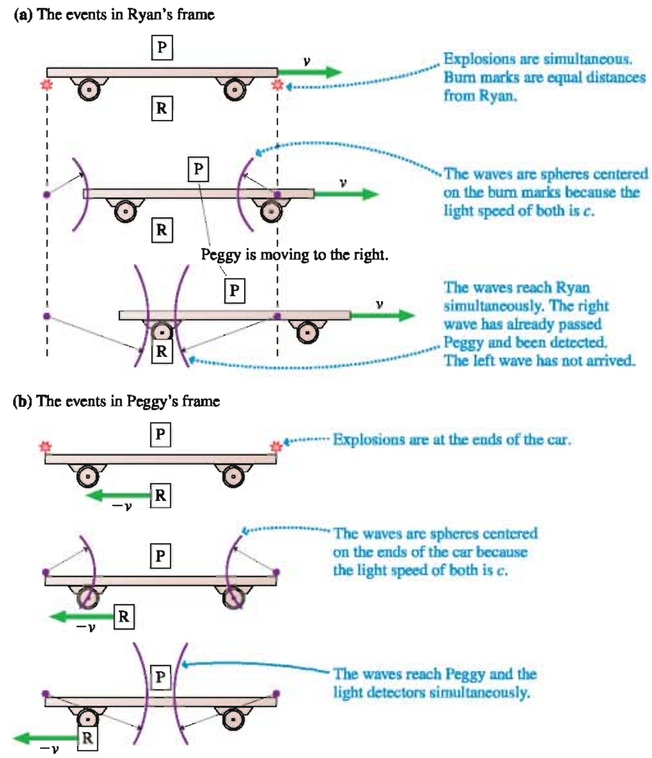
Now the light on top must be either green or red. *It can't be both!* Later, after the railroad car has stopped, Ryan and Peggy can place the box in front of them. Either it has a red light or a green light. Ryan can't see one color while Peggy sees the other. Hence we have a paradox. It's impossible for Peggy and Ryan both to be right. But who is wrong, and why?

What do we know with absolute certainty?

1. Ryan detected the flashes simultaneously.
2. Ryan was halfway between the firecrackers when they exploded.
3. The light from the two explosions traveled toward Ryan at equal speeds.

The conclusion that the explosions were simultaneous in Ryan's reference frame is unassailable. The light is green.

FIGURE 37.17 Exploding firecrackers seen in two different reference frames.



Peggy, however, made an assumption. It's a perfectly ordinary assumption, one that seems sufficiently obvious that you probably didn't notice, but an assumption nonetheless. Peggy assumed that the explosions were simultaneous.

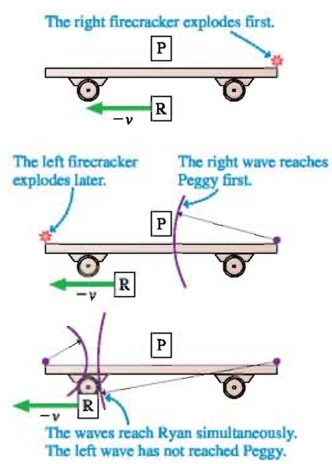
Didn't Ryan find them to be simultaneous? Indeed, he did. Suppose we call Ryan's reference frame S, the explosion on the right event R, and the explosion on the left event L. Ryan found that $t_R = t_L$. But Peggy has to use a different set of clocks, the clocks in her reference frame S′, to measure the times t'_R and t'_L at which the explosions occurred. The fact that $t_R = t_L$ in frame S does *not* allow us to conclude that $t'_R = t'_L$ in frame S′.

In fact, in frame S′ the right firecracker must explode *before* the left firecracker. Figure 37.17b, with its assumption about simultaneity, was incorrect. **FIGURE 37.18** shows the situation in Peggy's reference frame, with the right firecracker exploding first. Now the wave from the right reaches Peggy and the box first, as Ryan had concluded, and the light on top turns green.

One of the most disconcerting conclusions of relativity is that **two events occurring simultaneously in reference frame S are *not* simultaneous in any reference frame S′ moving relative to S.** This is called the **relativity of simultaneity.**

The two firecrackers *really* explode at the same instant of time in Ryan's reference frame. And the right firecracker *really* explodes first in Peggy's reference frame. It's not a matter of when they see the flashes. Our conclusion refers to the times at which the explosions actually occur.

FIGURE 37.18 The real sequence of events in Peggy's reference frame.



The paradox of Peggy and Ryan contains the essence of relativity, and it's worth careful thought. First, review the logic until you're certain that there *is* a paradox, a logical impossibility. Then convince yourself that the only way to resolve the paradox is to abandon the assumption that the explosions are simultaneous in Peggy's reference frame. If you understand the paradox and its resolution, you've made a big step toward understanding what relativity is all about.

STOP TO THINK 37.5 A tree and a pole are 3000 m apart. Each is hit by a bolt of lightning. Mark, who is standing at rest midway between the two, sees the two lightning bolts at the same instant of time. Nancy is flying her rocket at $v = 0.5c$ in the direction from the tree toward the pole. The lightning hits the tree just as she passes by it. Define event 1 to be "lightning strikes tree" and event 2 to be "lightning strikes pole." For Nancy, does event 1 occur before, after, or at the same time as event 2?

37.6 Time Dilation

17.1 Activ ONLINE Physics

The principle of relativity has driven us to the logical conclusion that time is not the same for two reference frames moving relative to each other. Our analysis thus far has been mostly qualitative. It's time to start developing some quantitative tools that will allow us to compare measurements in one reference frame to measurements in another reference frame.

FIGURE 37.19 The ticking of a light clock can be measured by experimenters in two different reference frames.

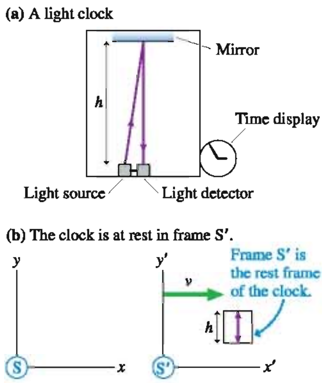


FIGURE 37.19a shows a special clock called a light clock. The light clock is a box with a light source at the bottom and a mirror at the top, separated by distance h. The light source emits a very short pulse of light that travels to the mirror and reflects back to a light detector beside the source. The clock advances one "tick" each time the detector receives a light pulse, and it immediately, with no delay, causes the light source to emit the next light pulse.

Our goal is to compare two measurements of the interval between two ticks of the clock: one taken by an experimenter standing next to the clock and the other by an experimenter moving with respect to the clock. To be specific, FIGURE 37.19b shows the clock at rest in reference frame S′. We call this the **rest frame** of the clock. Reference frame S′ moves to the right with velocity v relative to reference frame S.

Relativity requires us to measure *events*, so let's define event 1 to be the emission of a light pulse and event 2 to be the detection of that light pulse. Experimenters in both reference frames are able to measure where and when these events occur *in their frame*. In frame S, the time interval $\Delta t = t_2 - t_1$ is one tick of the clock. Similarly, one tick in frame S′ is $\Delta t' = t_2' - t_1'$.

To be sure we have a clear understanding of the relativity result, let's first do a classical analysis. In frame S′, the clock's rest frame, the light travels straight up and down, a total distance $2h$, at speed c. The time interval is $\Delta t' = 2h/c$.

FIGURE 37.20a shows the operation of the light clock as seen in frame S. The clock is moving to the right at speed v in S, thus the mirror moves distance $\frac{1}{2}v(\Delta t)$ during the time $\frac{1}{2}(\Delta t)$ in which the light pulse moves from the source to the mirror. The distance traveled by the light during this interval is $\frac{1}{2}u_{\text{light}}(\Delta t)$, where u_{light} is the speed of light in frame S. You can see from the vector addition in FIGURE 37.20b that the speed of light in frame S′ is $u_{\text{light}} = (c^2 + v^2)^{1/2}$. (Remember, this is a classical analysis in which the speed of light *does* depend on the motion of the reference frame relative to the light source.)

The Pythagorean theorem applied to the right triangle in Figure 37.20a is

$$h^2 + \left(\frac{1}{2}v\Delta t\right)^2 = \left(\frac{1}{2}u_{\text{light}}\Delta t\right)^2 = \left(\frac{1}{2}\sqrt{c^2 + v^2}\Delta t\right)^2$$
$$= \left(\frac{1}{2}c\Delta t\right)^2 + \left(\frac{1}{2}v\Delta t\right)^2 \qquad (37.4)$$

The term $(\frac{1}{2}v\Delta t)^2$ is common to both sides and cancels. Solving for Δt gives $\Delta t = 2h/c$, identical to $\Delta t'$. In other words, a classical analysis finds that the clock ticks at exactly the same rate in both frame S and frame S′. This shouldn't be surprising. There's only one kind of time in classical physics, measured the same by all experimenters independent of their motion.

The principle of relativity changes only one thing, but that change has profound consequences. According to the principle of relativity, light travels at the same speed in *all* inertial reference frames. In frame S′, the rest frame of the clock, the light simply goes straight up and back. The time of one tick,

$$\Delta t' = \frac{2h}{c} \qquad (37.5)$$

is unchanged from the classical analysis.

FIGURE 37.21 shows the light clock as seen in frame S. The difference from Figure 37.20a is that the light now travels along the hypotenuse at speed c. We can again use the Pythagorean theorem to write

$$h^2 + \left(\frac{1}{2}v\Delta t\right)^2 = \left(\frac{1}{2}c\Delta t\right)^2 \qquad (37.6)$$

Solving for Δt gives

$$\Delta t = \frac{2h/c}{\sqrt{1 - v^2/c^2}} = \frac{\Delta t'}{\sqrt{1 - v^2/c^2}} \qquad (37.7)$$

The time interval between two ticks in frame S is *not* the same as in frame S′.

It's useful to define $\beta = v/c$, the velocity as a fraction of the speed of light. For example, a reference frame moving with $v = 2.4 \times 10^8$ m/s has $\beta = 0.80$. In terms of β, Equation 37.7 is

$$\Delta t = \frac{\Delta t'}{\sqrt{1 - \beta^2}} \qquad (37.8)$$

NOTE ▶ The expression $(1 - v^2/c^2)^{1/2} = (1 - \beta^2)^{1/2}$ occurs frequently in relativity. The value of the expression is 1 when $v = 0$, and it steadily decreases to 0 as $v \to c$ (or $\beta \to 1$). The square root is an imaginary number if $v > c$, which would make Δt imaginary in Equation 37.8. Time intervals certainly have to be real numbers, suggesting that $v > c$ is not physically possible. One of the predictions of the theory of relativity, as you've undoubtedly heard, is that nothing can travel faster than the speed of light. Now you can begin to see why. We'll examine this topic more closely in Section 37.9. In the meantime, we'll require v to be less than c. ◀

FIGURE 37.20 A classical analysis of the light clock.

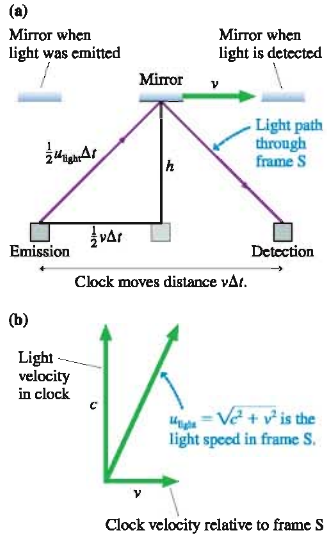

FIGURE 37.21 A light clock analysis in which the speed of light is the same in all reference frames.

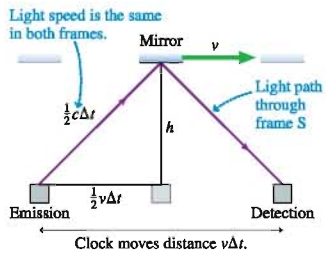


Proper Time

Frame S′ has one important distinction. It is the *one and only* inertial reference frame in which the clock is at rest. Consequently, it is the one and only inertial reference frame in which the times of both events—the emission of the light and the detection of the light—are measured by the *same* clock. You can see that the light pulse in Figure 37.19, the rest frame of the clock, starts and ends at the same position and can be measured by one clock. In Figure 37.21, the emission and detection take place at different positions in frame S and must be measured by different clocks.

The time interval between two events that occur at the *same position* is called the **proper time** $\Delta\tau$. Only one inertial reference frame measures the proper time, and it does so with a single clock that is present at both events. An inertial reference frame moving with velocity $v = \beta c$ relative to the proper time frame must use two clocks to measure the time interval because the two events occur at different positions. The time interval between the two events in this frame is

$$\Delta t = \frac{\Delta\tau}{\sqrt{1-\beta^2}} \geq \Delta\tau \qquad \text{(time dilation)} \qquad (37.9)$$

The "stretching out" of the time interval implied by Equation 37.9 is called **time dilation.** Time dilation is sometimes described by saying that "moving clocks run slow." This is not an accurate statement because it implies that some reference frames are "really" moving while others are "really" at rest. The whole point of relativity is that all inertial reference frames are equally valid, that all we know about reference frames is how they move relative to each other. A better description of time dilation is the statement that **the time interval between two ticks is the shortest in the reference frame in which the clock is at rest.** The time interval between two ticks is longer (i.e., the clock "runs slower") when it is measured in any reference frame in which the clock is moving.

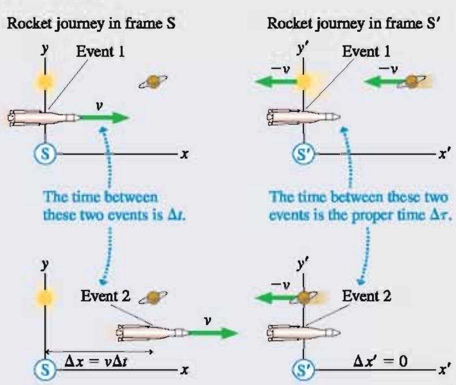
NOTE ▶ Equation 37.9 was derived using a light clock because the operation of a light clock is clear and easy to analyze. But the conclusion is really about time itself. *Any* clock, regardless of how it operates, behaves the same. ◀

EXAMPLE 37.5 From the sun to Saturn

Saturn is 1.43×10^{12} m from the sun. A rocket travels along a line from the sun to Saturn at a constant speed of $0.9c$ relative to the solar system. How long does the journey take as measured by an experimenter on earth? As measured by an astronaut on the rocket?

MODEL Let the solar system be in reference frame S and the rocket be in reference frame S′ that travels with velocity $v = 0.9c$ relative to S. Relativity problems must be stated in terms of *events*. Let event 1 be "the rocket and the sun coincide" (the experimenter on earth says that the rocket passes the sun; the astronaut on the rocket says that the sun passes the rocket) and event 2 be "the rocket and Saturn coincide."

FIGURE 37.22 Pictorial representation of the trip as seen in frames S and S′.



VISUALIZE FIGURE 37.22 shows the two events as seen from the two reference frames. Notice that the two events occur at the *same position* in S′, the position of the rocket, and consequently can be measured by *one* clock.

SOLVE The time interval measured in the solar system reference frame, which includes the earth, is simply

$$\Delta t = \frac{\Delta x}{v} = \frac{1.43 \times 10^{12}\ \text{m}}{0.9 \times (3.00 \times 10^8\ \text{m/s})} = 5300\ \text{s}$$

Relativity hasn't abandoned the basic definition $v = \Delta x/\Delta t$, although we do have to be sure that Δx and Δt are measured in just one reference frame and refer to the same two events.

How are things in the rocket's reference frame? The two events occur at the *same position* in S′ and can be measured by *one* clock, the clock at the origin. Thus the time measured by the astronauts is the *proper time* $\Delta\tau$ between the two events. We can use Equation 37.9 with $\beta = 0.9$ to find

$$\Delta\tau = \sqrt{1-\beta^2}\,\Delta t = \sqrt{1-0.9^2}\,(5300\ \text{s}) = 2310\ \text{s}$$

ASSESS The time interval measured between these two events by the astronauts is less than half the time interval measured by experimenters on earth. The difference has nothing to do with when earthbound astronomers *see* the rocket pass the sun and Saturn. Δt is the time interval from when the rocket actually passes the sun, as measured by a clock at the sun, until it actually passes Saturn, as measured by a synchronized clock at Saturn. The interval between *seeing* the events from earth, which would have to allow for light travel times, would be something other than 5300 s. Δt and $\Delta\tau$ are different because *time is different* in two reference frames moving relative to each other.

STOP TO THINK 37.6 Molly flies her rocket past Nick at constant velocity v. Molly and Nick both measure the time it takes the rocket, from nose to tail, to pass Nick. Which of the following is true?

a. Both Molly and Nick measure the same amount of time.
b. Molly measures a shorter time interval than Nick.
c. Nick measures a shorter time interval than Molly.

Experimental Evidence

Is there any evidence for the crazy idea that clocks moving relative to each other tell time differently? Indeed, there's plenty. An experiment in 1971 sent an atomic clock around the world on a jet plane while an identical clock remained in the laboratory. This was a difficult experiment because the traveling clock's speed was so small compared to c, but measuring the small differences between the time intervals was just barely within the capabilities of atomic clocks. It was also a more complex experiment than we've analyzed because the clock accelerated as it moved around a circle. Nonetheless, the traveling clock, upon its return, was 200 ns behind the clock that stayed at home, which was exactly as predicted by relativity.

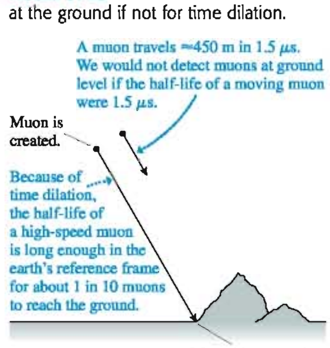
Very detailed studies have been done on unstable particles called *muons* that are created at the top of the atmosphere, at a height of about 60 km, when high-energy cosmic rays collide with air molecules. It is well known, from laboratory studies, that stationary muons decay with a *half-life* of 1.5 μs. That is, half the muons decay within 1.5 μs, half of those remaining decay in the next 1.5 μs, and so on. The decays can be used as a clock.

The muons travel down through the atmosphere at very nearly the speed of light. The time needed to reach the ground, assuming $v \approx c$, is $\Delta t \approx (60{,}000\text{ m})/(3 \times 10^8\text{ m/s}) = 200\ \mu\text{s}$. This is 133 half-lives, so the fraction of muons reaching the ground should be $\approx(\frac{1}{2})^{133} = 10^{-40}$. That is, only 1 out of every 10^{40} muons should reach the ground. In fact, experiments find that about 1 in 10 muons reach the ground, an experimental result that differs by a factor of 10^{39} from our prediction!

The discrepancy is due to time dilation. In FIGURE 37.23, the two events "muon is created" and "muon hits ground" take place at two different places in the earth's reference frame. However, these two events occur at the *same position* in the muon's reference frame. (The muon is like the rocket in Example 37.5.) Thus the muon's internal clock measures the proper time. The time-dilated interval $\Delta t = 200\ \mu\text{s}$ in the earth's reference frame corresponds to a proper time $\Delta\tau \approx 5\ \mu\text{s}$ in the muon's reference frame. That is, in the muon's reference frame it takes only 5 μs from creation at the top of the atmosphere until the ground runs into it. This is 3.3 half-lives, so the fraction of muons reaching the ground is $(\frac{1}{2})^{3.3} = 0.1$, or 1 out of 10. We wouldn't detect muons at the ground at all if not for time dilation.

The details are beyond the scope of this textbook, but dozens of high-energy particle accelerators around the world that study quarks and other elementary particles have been designed and built on the basis of Einstein's theory of relativity. The fact that they work exactly as planned is strong testimony to the reality of time dilation.

FIGURE 37.23 We wouldn't detect muons at the ground if not for time dilation.



The Twin Paradox

The most well-known relativity paradox is the twin paradox. George and Helen are twins. On their 25th birthday, Helen departs on a starship voyage to a distant star. Let's imagine, to be specific, that her starship accelerates almost instantly to a speed of $0.95c$ and that she travels to a star that is 9.5 light years (9.5 ly) from earth. Upon arriving, she discovers that the planets circling the star are inhabited by fierce aliens, so she immediately turns around and heads home at $0.95c$.

The global positioning system (GPS), which allows you to pinpoint your location anywhere in the world to within a few meters, uses a set of orbiting satellites. Because of their motion, the atomic clocks on these satellites keep time differently from clocks on the ground. To determine an accurate position, the software in your GPS receiver must carefully correct for time-dilation effects.

A **light year,** abbreviated ly, is the distance that light travels in one year. A light year is vastly larger than the diameter of the solar system. The distance between two neighboring stars is typically a few light years. For our purpose, we can write the speed of light as $c = 1$ ly/year. That is, light travels 1 light year per year.

This value for c allows us to determine how long, according to George and his fellow earthlings, it takes Helen to travel out and back. Her total distance is 19 ly and, due to her rapid acceleration and rapid turn-around, she travels essentially the entire distance at speed $v = 0.95c = 0.95$ ly/year. Thus the time she's away, as measured by George, is

$$\Delta t_G = \frac{19 \text{ ly}}{0.95 \text{ ly/year}} = 20 \text{ years} \tag{37.10}$$

George will be 45 years old when his sister Helen returns with tales of adventure.

While she's away, George takes a physics class and studies Einstein's theory of relativity. He realizes that time dilation will make Helen's clocks run more slowly than his clocks, which are at rest relative to him. Her heart—a clock—will beat fewer times and the minute hand on her watch will go around fewer times. In other words, she's aging more slowly than he is. Although she is his twin, she will be younger than he is when she returns.

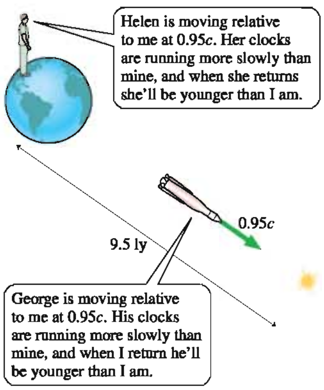
Calculating Helen's age is not hard. We simply have to identify Helen's clock, because it's always with Helen as she travels, as the clock that measures proper time $\Delta\tau$. From Equation 37.9,

$$\Delta t_H = \Delta\tau = \sqrt{1 - \beta^2}\,\Delta t_G = \sqrt{1 - 0.95^2}\,(20 \text{ years}) = 6.25 \text{ years} \tag{37.11}$$

George will have just celebrated his 45th birthday as he welcomes home his 31-year-and-3-month-old twin sister.

This may be unsettling because it violates our commonsense notion of time, but it's not a paradox. There's no logical inconsistency in this outcome. So why is it called "the twin paradox"? Read on.

FIGURE 37.24 The twin paradox.



Helen, knowing that she had quite of bit of time to kill on her journey, brought along several physics books to read. As she learns about relativity, she begins to think about George and her friends back on earth. Relative to her, they are all moving away at $0.95c$. Later they'll come rushing toward her at $0.95c$. Time dilation will cause their clocks to run more slowly than her clocks, which are at rest relative to her. In other words, as **FIGURE 37.24** shows, Helen concludes that people on earth are aging more slowly than she is. Alas, she will be much older than they when she returns.

Finally, the big day arrives. Helen lands back on earth and steps out of the starship. George is expecting Helen to be younger than he is. Helen is expecting George to be younger than she is.

Here's the paradox! It's logically impossible for each to be younger than the other at the time they are reunited. Where, then, is the flaw in our reasoning? It seems to be a symmetrical situation—Helen moves relative to George and George moves relative to Helen—but symmetrical reasoning has led to a conundrum.

But are the situations really symmetrical? George goes about his business day after day without noticing anything unusual. Helen, on the other hand, experiences three distinct periods during which the starship engines fire, she's crushed into her seat, and free dust particles that had been floating inside the starship are no longer, in the starship's reference frame, at rest or traveling in a straight line at constant speed. In other words, George spends the entire time in an inertial reference frame, *but Helen does not.* The situation is *not* symmetrical.

The principle of relativity applies *only* to inertial reference frames. Our discussion of time dilation was for inertial reference frames. Thus George's analysis and calculations are correct. Helen's analysis and calculations are *not* correct because she was trying to apply an inertial reference frame result to a noninertial reference frame.

Helen is younger than George when she returns. This is strange, but not a paradox. It is a consequence of the fact that time flows differently in two reference frames moving relative to each other.

37.7 Length Contraction

We've seen that relativity requires us to rethink our idea of time. Now let's turn our attention to the concepts of space and distance. Consider the rocket that traveled from the sun to Saturn in Example 37.5. FIGURE 37.25a shows the rocket moving with velocity v through the solar system reference frame S. We define $L = \Delta x = x_{Saturn} - x_{sun}$ as the distance between the sun and Saturn in frame S or, more generally, the *length* of the spatial interval between two points. The rocket's speed is $v = L/\Delta t$, where Δt is the time measured in frame S for the journey from the sun to Saturn.

Activ Physics 17.2

FIGURE 37.25 L and L' are the distances between the sun and Saturn in frames S and S'.

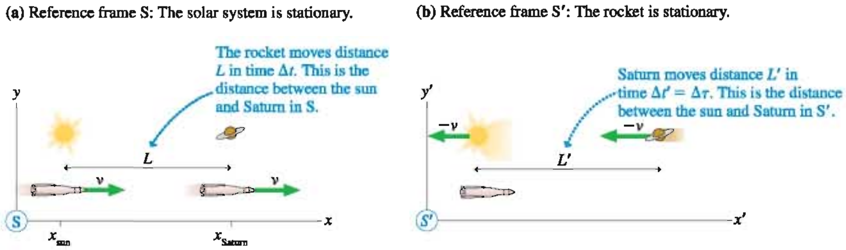


FIGURE 37.25b shows the situation in reference frame S', where the rocket is at rest. The sun and Saturn move to the left at speed $v = L'/\Delta t'$, where $\Delta t'$ is the time measured in frame S' for Saturn to travel distance L'.

Speed v is the relative speed between S and S' and is the same for experimenters in both reference frames. That is,

$$v = \frac{L}{\Delta t} = \frac{L'}{\Delta t'} \tag{37.12}$$

The time interval $\Delta t'$ measured in frame S' is the proper time $\Delta\tau$ because both events occur at the same position in frame S' and can be measured by one clock. We can use the time-dilation result, Equation 37.9, to relate $\Delta\tau$ measured by the astronauts to Δt measured by the earthbound scientists. Then Equation 37.12 becomes

$$\frac{L}{\Delta t} = \frac{L'}{\Delta\tau} = \frac{L'}{\sqrt{1-\beta^2}\,\Delta t} \tag{37.13}$$

The Δt cancels, and the distance L' in frame S' is

$$L' = \sqrt{1-\beta^2}\,L \tag{37.14}$$

Surprisingly, we find that **the distance between two objects in reference frame S' is *not the same* as the distance between the same two objects in reference frame S.**

Frame S, in which the distance is L, has one important distinction. It is the *one and only* inertial reference frame in which the objects are at rest. Experimenters in frame S can take all the time they need to measure L because the two objects aren't going anywhere. The distance L between two objects, or two points on one object, measured in the reference frame in which the objects are at rest is called the **proper length ℓ**. Only one inertial reference frame can measure the proper length.

The Stanford Linear Accelerator (SLAC) is a 2-mi-long electron accelerator. The accelerator's length is less than 1 m in the reference frame of the electrons.

We can use the proper length ℓ to write Equation 37.14 as

$$\boxed{L' = \sqrt{1-\beta^2}\,\ell \le \ell} \tag{37.15}$$

This "shrinking" of the distance between two objects, as measured by an experiment moving with respect to the objects, is called **length contraction.** Although we derived length contraction for the distance between two distinct objects, it applies equally well to the length of any physical object that stretches between two points along the x- and x'-axes. The length of an object is greatest in the reference frame in which the object is at rest. The object's length is less (i.e., the length is contracted) when it is measured in any reference frame in which the object is moving.

EXAMPLE 37.6 The distance from the sun to Saturn

In Example 37.5 a rocket traveled along a line from the sun to Saturn at a constant speed of $0.9c$ relative to the solar system. The Saturn-to-sun distance was given as 1.43×10^{12} m. What is the distance between the sun and Saturn in the rocket's reference frame?

MODEL Saturn and the sun are, at least approximately, at rest in the solar system reference frame S. Thus the given distance is the proper length ℓ.

SOLVE We can use Equation 37.15, to find the distance in the rocket's frame S′:

$$L' = \sqrt{1 - \beta^2}\,\ell = \sqrt{1 - 0.9^2}\,(1.43 \times 10^{12}\text{ m})$$
$$= 0.62 \times 10^{12}\text{ m}$$

ASSESS The sun-to-Saturn distance measured by the astronauts is less than half the distance measured by experimenters on earth. L' and ℓ are different because *space is different* in two reference frames moving relative to each other.

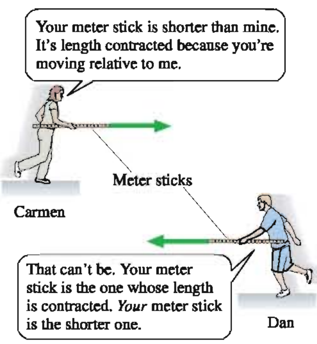
The conclusion that space is different in reference frames moving relative to each other is a direct consequence of the fact that time is different. Experimenters in both reference frames agree on the relative velocity v, leading to Equation 37.12: $v = L/\Delta t = L'/\Delta t'$. We had already learned that $\Delta t' < \Delta t$ because of time dilation. Thus L' *has* to be less than L. That is the only way experimenters in the two reference frames can reconcile their measurements.

To be specific, the earthly experimenters in Examples 37.5 and 37.6 find that the rocket takes 5300 s to travel the 1.43×10^{12} m between the sun and Saturn. The rocket's speed is $v = L/\Delta t = 2.7 \times 10^8$ m/s $= 0.9c$. The astronauts in the rocket find that it takes only 2310 s for Saturn to reach them after the sun has passed by. But there's no conflict, because they also find that the distance is only 0.62×10^{12} m. Thus Saturn's speed toward them is $v = L'/\Delta t' = (0.62 \times 10^{12}\text{ m})/(2310\text{ s}) = 2.7 \times 10^8$ m/s $= 0.9c$.

Another Paradox?

Carmen and Dan are in their physics lab room. They each select a meter stick, lay the two side by side, and agree that the meter sticks are exactly the same length. Then, for an extra-credit project, they go outside and run past each other, in opposite directions, at a relative speed $v = 0.9c$. FIGURE 37.26 shows their experiment and a portion of their conversation.

FIGURE 37.26 Carmen and Dan each measure the length of the other's meter stick as they move relative to each other.



Now, Dan's meter stick can't be both longer and shorter than Carmen's meter stick. Is this another paradox? No! Relativity allows us to compare the *same* events as they're measured in two different reference frames. This did lead to a real paradox when Peggy rolled past Ryan on the train. There the signal light on the box turns green (a single event) or it doesn't, and Peggy and Ryan have to agree about it. But the events by which Dan measures the length (in Dan's frame) of Carmen's meter stick are *not the same events* as those by which Carmen measures the length (in Carmen's frame) of Dan's meter stick.

There's no conflict between their measurements. In Dan's reference frame, Carmen's meter stick has been length contracted and is less than 1 m in length. In Carmen's reference frame, Dan's meter stick has been length contracted and is less than 1 m in length. If this weren't the case, if both agreed that one of the meter sticks was shorter than the other, then we could tell which reference frame was "really" moving and which was "really" at rest. But the principle of relativity doesn't allow us to make

that distinction. Each is moving relative to the other, so each should make the same measurement for the length of the other's meter stick.

The Spacetime Interval

Forget relativity for a minute and think about ordinary geometry. FIGURE 37.27 shows two ordinary coordinate systems. They are identical except for the fact that one has been rotated relative to the other. A student using the xy-system would measure coordinates (x_1, y_1) for point 1 and (x_2, y_2) for point 2. A second student, using the $x'y'$-system, would measure (x_1', y_1') and (x_2', y_2').

The students soon find that none of their measurements agree. That is, $x_1 \neq x_1'$ and so on. Even the intervals are different: $\Delta x \neq \Delta x'$ and $\Delta y \neq \Delta y'$. Each is a perfectly valid coordinate system, giving no reason to prefer one over the other, but each yields different measurements.

Is there *anything* on which the two students can agree? Yes, there is. The distance d between points 1 and 2 is independent of the coordinates. We can state this mathematically as

$$d^2 = (\Delta x)^2 + (\Delta y)^2 = (\Delta x')^2 + (\Delta y')^2 \qquad (37.16)$$

The quantity $(\Delta x)^2 + (\Delta y)^2$ is called an **invariant** in geometry because it has the same value in any Cartesian coordinate system.

Returning to relativity, is there an invariant in the spacetime coordinates, some quantity that has the *same value* in all inertial reference frames? There is, and to find it let's return to the light clock of Figure 37.21. FIGURE 37.28 shows the light clock as seen in reference frames S′ and S″. The speed of light is the same in both frames, even though both are moving with respect to each other and with respect to the clock.

Notice that the clock's height h is common to both reference frames. Thus

$$h^2 = \left(\frac{1}{2}c\Delta t'\right)^2 - \left(\frac{1}{2}\Delta x'\right)^2 = \left(\frac{1}{2}c\Delta t''\right)^2 - \left(\frac{1}{2}\Delta x''\right)^2 \qquad (37.17)$$

The factor $\frac{1}{2}$ cancels, allowing us to write

$$c^2(\Delta t')^2 - (\Delta x')^2 = c^2(\Delta t'')^2 - (\Delta x'')^2 \qquad (37.18)$$

Let us define the **spacetime interval** s between two events to be

$$s^2 = c^2(\Delta t)^2 - (\Delta x)^2 \qquad (37.19)$$

What we've shown in Equation 37.18 is that **the spacetime interval s has the same value in all inertial reference frames.** That is, the spacetime interval between two events is an invariant. It is a value that all experimenters, in all reference frames, can agree upon.

FIGURE 37.27 Distance d is the same in both coordinate systems.

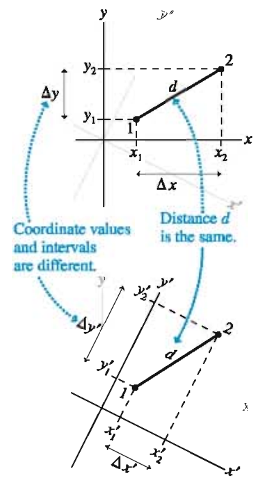


FIGURE 37.28 The light clock seen by experimenters in reference frames S′ and S″.

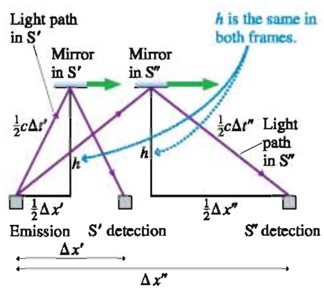


EXAMPLE 37.7 Using the spacetime interval

A firecracker explodes at the origin of an inertial reference frame. Then, 2.0 μs later, a second firecracker explodes 300 m away. Astronauts in a passing rocket measure the distance between the explosions to be 200 m. According to the astronauts, how much time elapses between the two explosions?

MODEL The spacetime coordinates of two events are measured in two different inertial reference frames. Call the reference frame of the ground S and the reference frame of the rocket S′. The spacetime interval between these two events is the same in both reference frames.

SOLVE The spacetime interval (or, rather, its square) in frame S is

$$s^2 = c^2(\Delta t)^2 - (\Delta x)^2 = (600\text{ m})^2 - (300\text{ m})^2 = 270{,}000\text{ m}^2$$

where we used $c = 300$ m/μs to determine that $c\Delta t = 600$ m. The spacetime interval has the same value in frame S′. Thus

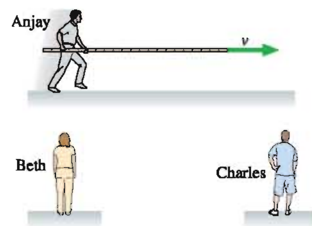
$$s^2 = 270{,}000\text{ m}^2 = c^2(\Delta t')^2 - (\Delta x')^2$$
$$= c^2(\Delta t')^2 - (200\text{ m})^2$$

This is easily solved to give $\Delta t' = 1.85$ μs.

ASSESS The two events are closer together in both space and time in the rocket's reference frame than in the reference frame of the ground.

Einstein's legacy, according to popular culture, was the discovery that "everything is relative." But it's not so. Time intervals and space intervals may be relative, as were the intervals Δx and Δy in the purely geometric analogy with which we opened this section, but some things are *not* relative. In particular, the spacetime interval s between two events is not relative. It is a well-defined number, agreed on by experimenters in each and every inertial reference frame.

STOP TO THINK 37.7 Beth and Charles are at rest relative to each other. Anjay runs past at velocity v while holding a long pole parallel to his motion. Anjay, Beth, and Charles each measure the length of the pole at the instant Anjay passes Beth. Rank in order, from largest to smallest, the three lengths L_A, L_B, and L_C.



37.8 The Lorentz Transformations

The Galilean transformation $x' = x - vt$ of classical relativity lets us calculate the position x' of an event in frame S′ if we know its position x in frame S. Classical relativity, of course, assumes that $t' = t$. Is there a similar transformation in relativity that would allow us to calculate an event's spacetime coordinates (x', t') in frame S′ if we know their values (x, t) in frame S? Such a transformation would need to satisfy three conditions:

1. Agree with the Galilean transformations in the low-speed limit $v \ll c$.
2. Transform not only spatial coordinates but also time coordinates.
3. Ensure that the speed of light is the same in all reference frames.

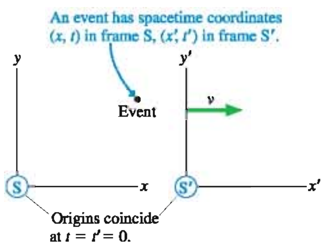


FIGURE 37.29 The spacetime coordinates of an event are measured in inertial reference frames S and S′.

We'll continue to use reference frames in the standard orientation of **FIGURE 37.29**. The motion is parallel to the x- and x'-axes, and we *define* $t = 0$ and $t' = 0$ as the instant when the origins of S and S′ coincide.

The requirement that a new transformation agree with the Galilean transformation when $v \ll c$ suggests that we look for a transformation of the form

$$x' = \gamma(x - vt) \quad \text{and} \quad x = \gamma(x' + vt') \tag{37.20}$$

where γ is a dimensionless function of velocity that satisfies $\gamma \to 1$ as $v \to 0$.

To determine γ, we consider the following two events:

Event 1: A flash of light is emitted from the origin of both reference frames ($x = x' = 0$) at the instant they coincide ($t = t' = 0$).

Event 2: The light strikes a light detector. The spacetime coordinates of this event are (x, t) in frame S and (x', t') in frame S′.

Light travels at speed c in both reference frames, so the positions of event 2 are $x = ct$ in S and $x' = ct'$ in S′. Substituting these expressions for x and x' into Equation 37.20 gives

$$\begin{aligned} ct' &= \gamma(ct - vt) = \gamma(c - v)t \\ ct &= \gamma(ct' + vt') = \gamma(c + v)t' \end{aligned} \tag{37.21}$$

We solve the first equation for t', by dividing by c, then substitute this result for t' into the second:

$$ct = \gamma(c + v)\frac{\gamma(c - v)t}{c} = \gamma^2(c^2 - v^2)\frac{t}{c}$$

The t cancels, leading to

$$\gamma^2 = \frac{c^2}{c^2 - v^2} = \frac{1}{1 - v^2/c^2}$$

Thus the γ that "works" in the proposed transformation of Equation 37.20 is

$$\gamma = \frac{1}{\sqrt{1 - v^2/c^2}} = \frac{1}{\sqrt{1 - \beta^2}} \tag{37.22}$$

You can see that $\gamma \to 1$ as $v \to 0$, as expected.

The transformation between t and t' is found by requiring that $x = x$ if you use Equation 37.20 to transform a position from S to S′ and then back to S. The details will be left for a homework problem. Another homework problem will let you demonstrate that the y and z measurements made perpendicular to the relative motion are not affected by the motion. We tacitly assumed this condition in our analysis of the light clock.

The full set of equations are called the **Lorentz transformations.** They are

$$\begin{aligned} x' &= \gamma(x - vt) & x &= \gamma(x' + vt') \\ y' &= y & y &= y' \\ z' &= z & z &= z' \\ t' &= \gamma(t - vx/c^2) & t &= \gamma(t' + vx'/c^2) \end{aligned} \tag{37.23}$$

The Lorentz transformations transform the spacetime coordinates of *one* event. Compare these to the Galilean transformation equations in Equations 37.1.

NOTE ► These transformations are named after the Dutch physicist H. A. Lorentz, who derived them prior to Einstein. Lorentz was close to discovering special relativity, but he didn't recognize that our concepts of space and time have to be changed before these equations can be properly interpreted. ◄

Using Relativity

Relativity is phrased in terms of *events;* hence relativity problems are solved by interpreting the problem statement in terms of specific events.

PROBLEM-SOLVING STRATEGY 37.1 Relativity

MP

MODEL Frame the problem in terms of events, things that happen at a specific place and time.

VISUALIZE A pictorial representation defines the reference frames.

- Sketch the reference frames, showing their motion relative to each other.
- Show events. Identify objects that are moving with respect to the reference frames.
- Identify any proper time intervals and proper lengths. These are measured in an object's rest frame.

SOLVE The mathematical representation is based on the Lorentz transformations, but not every problem requires the full transformation equations.

- Problems about time intervals can often be solved using time dilation: $\Delta t = \gamma \Delta \tau$.
- Problems about distances can often be solved using length contraction: $L = \ell/\gamma$.

ASSESS Are the results consistent with Galilean relativity when $v \ll c$?

EXAMPLE 37.8 Ryan and Peggy revisited

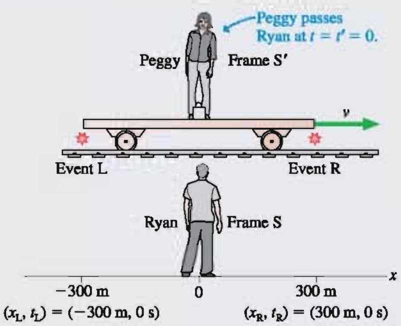
Peggy is standing in the center of a long, flat railroad car that has firecrackers tied to both ends. The car moves past Ryan, who is standing on the ground, with velocity $v = 0.8c$. Flashes from the exploding firecrackers reach him simultaneously 1.0 μs after the instant that Peggy passes him, and he later finds burn marks on the track 300 m to either side of where he had been standing.

a. According to Ryan, what is the distance between the two explosions, and at what times do the explosions occur relative to the time that Peggy passes him?
b. According to Peggy, what is the distance between the two explosions, and at what times do the explosions occur relative to the time that Ryan passes her?

MODEL Let the explosion on Ryan's right, the direction in which Peggy is moving, be event R. The explosion on his left is event L.

VISUALIZE Peggy and Ryan are in inertial reference frames. As FIGURE 37.30 shows, Peggy's frame S′ is moving with $v = 0.8c$ relative to Ryan's frame S. We've defined the reference frames such that Peggy and Ryan are at the origins. The instant they pass, by definition, is $t = t' = 0$ s. The two events are shown in Ryan's reference frame.

FIGURE 37.30 A pictorial representation of the reference frames and events.



SOLVE a. The two burn marks tell Ryan that the distance between the explosions was $L = 600$ m. Light travels at $c = 300$ m/μs, and the burn marks are 300 m on either side of him, so Ryan can determine that each explosion took place 1.0 μs before he saw the flash. But this was the instant of time that Peggy passed him, so Ryan concludes that the explosions were simultaneous with each other and with Peggy's passing him. The spacetime coordinates of the two events in frame S are $(x_R, t_R) = (300 \text{ m}, 0\ \mu\text{s})$ and $(x_L, t_L) = (-300 \text{ m}, 0\ \mu\text{s})$.

b. We already know, from our qualitative analysis in Section 37.5, that the explosions are *not* simultaneous in Peggy's reference frame. Event R happens before event L in S′, but we don't know how they compare to the time at which Ryan passes Peggy. We can now use the Lorentz transformations to relate the spacetime coordinates of these events as measured by Ryan to the spacetime coordinates as measured by Peggy. Using $v = 0.8c$, we find that γ is

$$\gamma = \frac{1}{\sqrt{1 - v^2/c^2}} = \frac{1}{\sqrt{1 - 0.8^2}} = 1.667$$

For event L, the Lorentz transformations are

$$x'_L = 1.667((-300 \text{ m}) - (0.8c)(0\ \mu\text{s})) = -500 \text{ m}$$

$$t'_L = 1.667((0\ \mu\text{s}) - (0.8c)(-300 \text{ m})/c^2) = 1.33\ \mu\text{s}$$

And for event R,

$$x'_R = 1.667((300 \text{ m}) - (0.8c)(0\ \mu\text{s})) = 500 \text{ m}$$

$$t'_R = 1.667((0\ \mu\text{s}) - (0.8c)(300 \text{ m})/c^2) = -1.33\ \mu\text{s}$$

According to Peggy, the two explosions occur 1000 m apart. Furthermore, the first explosion, on the right, occurs 1.33 μs before Ryan passes her at $t' = 0$ s. The second, on the left, occurs 1.33 μs after Ryan goes by.

ASSESS Events that are simultaneous in frame S are *not* simultaneous in frame S′. The results of the Lorentz transformations agree with our earlier qualitative analysis.

A follow-up discussion of Example 37.8 is worthwhile. Because Ryan moves at speed $v = 0.8c = 240$ m/μs relative to Peggy, he moves 320 m during the 1.33 μs between the first explosion and the instant he passes Peggy, then another 320 m before the second explosion. Gathering this information together, FIGURE 37.31 shows the sequence of events in Peggy's reference frame.

The firecrackers define the ends of the railroad car, so the 1000 m distance between the explosions in Peggy's frame is the car's length L' in frame S′. The car is at rest in frame S′, hence length L' is the proper length: $\ell = 1000$ m. Ryan is measuring the length of a moving object, so he should see the car length contracted to

$$L = \sqrt{1 - \beta^2}\,\ell = \frac{\ell}{\gamma} = \frac{1000 \text{ m}}{1.667} = 600 \text{ m}$$

And, indeed, that is exactly the distance Ryan measured between the burn marks.

Finally, we can calculate the spacetime interval s between the two events. According to Ryan,

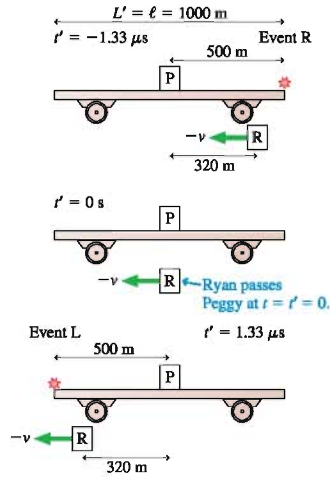
$$s^2 = c^2(\Delta t^2) - (\Delta x)^2 = c^2(0\ \mu\text{s})^2 - (600\ \text{m})^2 = -(600\ \text{m})^2$$

Peggy computes the spacetime interval to be

$$s^2 = c^2(\Delta t')^2 - (\Delta x')^2 = c^2(2.67\ \mu\text{s})^2 - (1000\ \text{m})^2 = -(600\ \text{m})^2$$

Their calculations of the spacetime interval agree, showing that s really is an invariant, but notice that s itself is an imaginary number.

FIGURE 37.31 The sequence of events as seen in Peggy's reference frame.



Length

We've already introduced the idea of length contraction, but we didn't precisely define just what we mean by the *length* of a moving object. The length of an object at rest is clear because we can take all the time we need to measure it with meter sticks, surveying tools, or whatever we need. But how can we give clear meaning to the length of a moving object?

A reasonable definition of an object's length is the distance $L = \Delta x = x_R - x_L$ between the right and left ends when the positions x_R and x_L are measured *at the same time t*. In other words, length is the distance spanned by the object at *one instant* of time. Measuring an object's length requires *simultaneous* measurements of two positions (i.e., two events are required); hence the result won't be known until the information from two spatially separated measurements can be brought together.

FIGURE 37.32 shows an object traveling through reference frame S with velocity v. The object is at rest in reference frame S′ that travels with the object at velocity v; hence the length in frame S′ is the proper length ℓ. That is, $\Delta x' = x'_R - x'_L = \ell$ in frame S′.

At time t, an experimenter (and his or her assistants) in frame S makes simultaneous measurements of the positions x_R and x_L of the ends of the object. The difference $\Delta x = x_R - x_L = L$ is the length in frame S. The Lorentz transformations of x_R and x_L are

$$x'_R = \gamma(x_R - vt)$$
$$x'_L = \gamma(x_L - vt) \tag{37.24}$$

where, it is important to note, t is the *same* for both because the measurements are simultaneous.

Subtracting the second equation from the first, we find

$$x'_R - x'_L = \ell = \gamma(x_R - x_L) = \gamma L = \frac{L}{\sqrt{1 - \beta^2}}$$

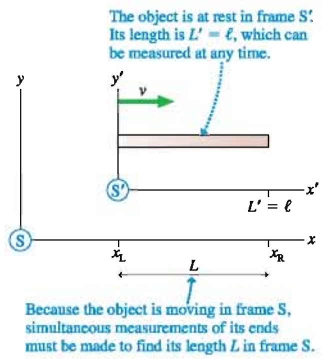
Solving for L, we find, in agreement with Equation 37.15, that

$$L = \sqrt{1 - \beta^2}\,\ell \tag{37.25}$$

This analysis has accomplished two things. First, by giving a precise definition of length, we've put our length-contraction result on a firmer footing. Second, we've had good practice at relativistic reasoning using the Lorentz transformation.

NOTE ▶ Length contraction does not tell us how an object would *look*. The visual appearance of an object is determined by light waves that arrive simultaneously at the eye. These waves left points on the object at different times (i.e., *not* simultaneously) because they had to travel different distances to the eye. The analysis needed to determine an object's visual appearance is considerably more complex. Length and length contraction are concerned only with the *actual* length of the object at one instant of time. ◀

FIGURE 37.32 The length of an object is the distance between *simultaneous* measurements of the positions of the end points.



The Binomial Approximation

The binomial approximation

If $x \ll 1$, then $(1 + x)^n \approx 1 + nx$

You've met the binomial approximation earlier in this text and in your calculus class. The binomial approximation is useful when we need to calculate a relativistic expression for a nonrelativistic velocity $v \ll c$. Because $v^2/c^2 \ll 1$ in these cases, we can write

$$\text{If } v \ll c: \begin{cases} \sqrt{1-\beta^2} = (1 - v^2/c^2)^{1/2} \approx 1 - \dfrac{1}{2}\dfrac{v^2}{c^2} \\ \gamma = \dfrac{1}{\sqrt{1-\beta^2}} = (1 - v^2/c^2)^{-1/2} \approx 1 + \dfrac{1}{2}\dfrac{v^2}{c^2} \end{cases} \tag{37.26}$$

The following example illustrates the use of the binomial approximation.

EXAMPLE 37.9 The shrinking school bus

An 8.0-m-long school bus drives past at 30 m/s. By how much is its length contracted?

MODEL The school bus is at rest in an inertial reference frame S′ moving at velocity $v = 30$ m/s relative to the ground frame S. The given length, 8.0 m, is the proper length ℓ in frame S′.

SOLVE In frame S, the school bus is length contracted to

$$L = \sqrt{1-\beta^2}\,\ell$$

The bus's velocity v is much less than c, so we can use the binomial approximation to write

$$L \approx \left(1 - \frac{1}{2}\frac{v^2}{c^2}\right)\ell = \ell - \frac{1}{2}\frac{v^2}{c^2}\ell$$

The *amount* of the length contraction is

$$\ell - L = \frac{1}{2}\frac{v^2}{c^2}\ell = \frac{1}{2}\left(\frac{30\text{ m/s}}{3.0 \times 10^8\text{ m/s}}\right)^2 (8.0\text{ m})$$
$$= 4.0 \times 10^{-14}\text{ m} = 40\text{ fm}$$

where 1 fm = 1 femtometer = 10^{-15} m.

ASSESS The bus "shrinks" by only slightly more than the diameter of the nucleus of an atom. It's no wonder that we're not aware of length contraction in our everyday lives. If you had tried to calculate this number exactly, your calculator would have shown $\ell - L = 0$ because the difference between ℓ and L shows up only in the 14th decimal place. A scientific calculator determines numbers to 10 or 12 decimal places, but that isn't sufficient to show the difference. The binomial approximation provides an invaluable tool for finding the very tiny difference between two numbers that are nearly identical.

The Lorentz Velocity Transformations

FIGURE 37.33 The velocity of a moving object is measured to be u in frame S and u' in frame S′.

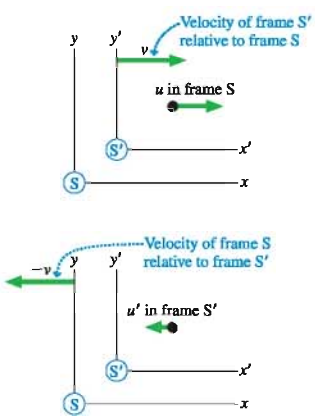


FIGURE 37.33 shows an object that is moving in both reference frame S and reference frame S′. Experimenters in frame S determine that the object's velocity is u, while experimenters in frame S′ find it to be u'. For simplicity, we'll assume that the object moves parallel to the x- and x'-axes.

The Galilean velocity transformation $u' = u - v$ was found by taking the time derivative of the position transformation. We can do the same with the Lorentz transformation if we take the derivative with respect to the time in each frame. Velocity u' in frame S′ is

$$u' = \frac{dx'}{dt'} = \frac{d(\gamma(x - vt))}{d(\gamma(t - vx/c^2))} \tag{37.27}$$

where we've used the Lorentz transformations for position x' and time t'.

Carrying out the differentiation gives

$$u' = \frac{\gamma(dx - v\,dt)}{\gamma(dt - v\,dx/c^2)} = \frac{dx/dt - v}{1 - v(dx/dt)/c^2} \tag{37.28}$$

But dx/dt is u, the object's velocity in frame S, leading to

$$u' = \frac{u - v}{1 - uv/c^2} \tag{37.29}$$

You can see that Equation 37.29 reduces to the Galilean transformation $u' = u - v$ when $v \ll c$, as expected.

The transformation from S′ to S is found by reversing the sign of v. Altogether,

$$u' = \frac{u - v}{1 - uv/c^2} \quad \text{and} \quad u = \frac{u' + v}{1 + u'v/c^2} \tag{37.30}$$

Equations 37.30 are the Lorentz velocity transformation equations.

NOTE ▶ It is important to distinguish carefully between v, which is the relative velocity between two reference frames, and u and u', which are the velocities of an *object* as measured in the two different reference frames. ◀

EXAMPLE 37.10 A really fast bullet

A rocket flies past the earth at $0.90c$. As it goes by, the rocket fires a bullet in the forward direction at $0.95c$ with respect to the rocket. What is the bullet's speed with respect to the earth?

MODEL The rocket and the earth are inertial reference frames. Let the earth be frame S and the rocket be frame S′. The velocity of frame S′ relative to frame S is $v = 0.90c$. The bullet's velocity in frame S′ is $u' = 0.95c$.

SOLVE We can use the Lorentz velocity transformation to find

$$u = \frac{u' + v}{1 + u'v/c^2} = \frac{0.95c + 0.90c}{1 + (0.95c)(0.90c)/c^2} = 0.997c$$

The bullet's speed with respect to the earth is 99.7% of the speed of light.

NOTE ▶ Many relativistic calculations are much easier when velocities are specified as a fraction of c. ◀

ASSESS In Newtonian mechanics, the Galilean transformation of velocity would give $u = 1.85c$. Now, despite the very high speed of the rocket and of the bullet with respect to the rocket, the bullet's speed with respect to the earth remains less than c. This is yet more evidence that objects cannot exceed the speed of light.

Suppose the rocket in Example 37.10 fired a laser beam in the forward direction as it traveled past the earth at velocity v. The laser beam would travel away from the rocket at speed $u' = c$ in the rocket's reference frame S′. What is the laser beam's speed in the earth's frame S? According to the Lorentz velocity transformation, it must be

$$u = \frac{u' + v}{1 + u'v/c^2} = \frac{c + v}{1 + cv/c^2} = \frac{c + v}{1 + v/c} = \frac{c + v}{(c + v)/c} = c \tag{37.31}$$

Light travels at speed c in both frame S and frame S′. This important consequence of the principle of relativity is "built into" the Lorentz transformations.

37.9 Relativistic Momentum

In Newtonian mechanics, the total momentum of a system is a conserved quantity. Further, as we've seen, the law of conservation of momentum, $P_f = P_i$, is true in all inertial reference frames *if* the particle velocities in different reference frames are related by the Galilean velocity transformations.

The difficulty, of course, is that the Galilean transformations are not consistent with the principle of relativity. It is a reasonable approximation when all velocities are very much less than c, but the Galilean transformations fail dramatically as velocities approach c. It's not hard to show that $P'_f \neq P'_i$ if the particle velocities in frame S′ are related to the particle velocities in frame S by the Lorentz transformations.

There are two possibilities:

1. The so-called law of conservation of momentum is not really a law of physics. It is approximately true at low velocities but fails as velocities approach the speed of light.
2. The law of conservation of momentum really is a law of physics, but the expression $p = mu$ is not the correct way to calculate momentum when the particle velocity u becomes a significant fraction of c.

Momentum conservation is such a central and important feature of mechanics that it seems unlikely to fail in relativity.

The classical momentum, for one-dimensional motion, is $p = mu = m(\Delta x/\Delta t)$. Δt is the time to move distance Δx. That seemed clear enough within a Newtonian framework, but now we've learned that experimenters in different reference frames disagree about the amount of time needed. So whose Δt should we use?

One possibility is to use the time measured *by the particle.* This is the proper time $\Delta\tau$ because the particle is at rest in its own reference frame and needs only one clock. With this in mind, let's redefine the momentum of a particle of mass m moving with velocity $u = \Delta x/\Delta t$ to be

$$p = m\frac{\Delta x}{\Delta\tau} \tag{37.32}$$

We can relate this new expression for p to the familiar Newtonian expression by using the time-dilation result $\Delta\tau = (1 - u^2/c^2)^{1/2}\Delta t$ to relate the proper time interval measured by the particle to the more practical time interval Δt measured by experimenters in frame S. With this substitution, Equation 37.32 becomes

$$p = m\frac{\Delta x}{\Delta\tau} = m\frac{\Delta x}{\sqrt{1 - u^2/c^2}\,\Delta t} = \frac{mu}{\sqrt{1 - u^2/c^2}} \tag{37.33}$$

You can see that Equation 37.33 reduces to the classical expression $p = mu$ when the particle's speed $u \ll c$. That is an important requirement, but whether this is the "correct" expression for p depends on whether the total momentum P is conserved when the velocities of a system of particles are transformed with the Lorentz velocity transformation equations. The proof is rather long and tedious, so we will assert, without actual proof, that the momentum defined in Equation 37.33 does, indeed, transform correctly. **The law of conservation of momentum is still valid in all inertial reference frames *if* the momentum of each particle is calculated with Equation 37.33.**

The factor that multiplies mu in Equation 37.33 looks much like the factor γ in the Lorentz transformation equations for x and t, but there's one very important difference. The v in the Lorentz transformation equations is the velocity of a *reference frame.* The u in Equation 37.33 is the velocity of a particle moving *in* a reference frame.

With this distinction in mind, let's define the quantity

$$\gamma_p = \frac{1}{\sqrt{1 - u^2/c^2}} \tag{37.34}$$

where the subscript p indicates that this is γ for a particle, not for a reference frame. In frame S′, where the particle moves with velocity u', the corresponding expression would be called γ_p'. With this definition of γ_p, the momentum of a particle is

$$p = \gamma_p mu \tag{37.35}$$

EXAMPLE 37.11 Momentum of a subatomic particle

Electrons in a particle accelerator reach a speed of $0.999c$ relative to the laboratory. One collision of an electron with a target produces a muon that moves forward with a speed of $0.95c$ relative to the laboratory. The muon mass is 1.90×10^{-28} kg. What is the muon's momentum in the laboratory frame and in the frame of the electron beam?

MODEL Let the laboratory be reference frame S. The reference frame S′ of the electron beam (i.e., a reference frame in which the electrons are at rest) moves in the direction of the electrons at $v = 0.999c$. The muon velocity in frame S is $u = 0.95c$.

SOLVE γ_p for the muon in the laboratory reference frame is

$$\gamma_p = \frac{1}{\sqrt{1 - u^2/c^2}} = \frac{1}{\sqrt{1 - 0.95^2}} = 3.20$$

Thus the muon's momentum in the laboratory is

$$p = \gamma_p mu = (3.20)(1.90 \times 10^{-28}\ \text{kg})(0.95 \times 3.00 \times 10^8\ \text{m/s})$$
$$= 1.73 \times 10^{-19}\ \text{kgm/s}$$

The momentum is a factor of 3.2 larger than the Newtonian momentum mu. To find the momentum in the electron-beam refer-

ence frame, we must first use the velocity transformation equation to find the muon's velocity in frame S′:

$$u' = \frac{u - v}{1 - uv/c^2} = \frac{0.95c - 0.999c}{1 - (0.95c)(0.999c)/c^2} = -0.962c$$

In the laboratory frame, the faster electrons are overtaking the slower muon. Hence the muon's velocity in the electron-beam frame is negative. γ'_p for the muon in frame S′ is

$$\gamma'_p = \frac{1}{\sqrt{1 - u'^2/c^2}} = \frac{1}{\sqrt{1 - 0.962^2}} = 3.66$$

The muon's momentum in the electron-beam reference frame is

$$\begin{aligned} p' &= \gamma'_p m u' \\ &= (3.66)(1.90 \times 10^{-28}\,\text{kg})(-0.962 \times 3.00 \times 10^8\,\text{m/s}) \\ &= -2.01 \times 10^{-19}\,\text{kg m/s} \end{aligned}$$

ASSESS From the laboratory perspective, the muon moves only slightly slower than the electron beam. But it turns out that the muon moves faster with respect to the electrons, although in the opposite direction, than it does with respect to the laboratory.

The Cosmic Speed Limit

FIGURE 37.34a is a graph of momentum versus velocity. For a Newtonian particle, with $p = mu$, the momentum is directly proportional to the velocity. The relativistic expression for momentum agrees with the Newtonian value if $u \ll c$, but p approaches ∞ as $u \to c$.

The implications of this graph become clear when we relate momentum to force. Consider a particle subjected to a constant force, such as a rocket that never runs out of fuel. If F is constant, we can see from $F = dp/dt$ that the momentum is $p = Ft$. If Newtonian physics were correct, a particle would go faster and faster as its velocity $u = p/m = (F/m)t$ increased without limit. But the relativistic result, shown in **FIGURE 37.34b**, is that the particle's velocity asymptotically approaches the speed of light ($u \to c$) as p approaches ∞. Relativity gives a very different outcome than Newtonian mechanics.

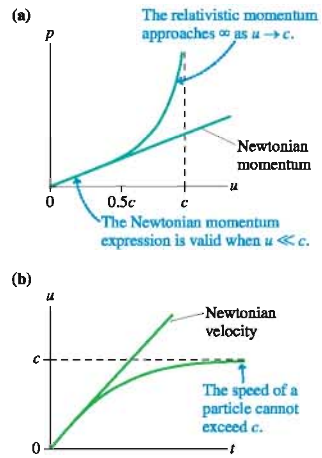

FIGURE 37.34 The speed of a particle cannot reach the speed of light.

The speed c is a "cosmic speed limit" for material particles. A force cannot accelerate a particle to a speed higher than c because the particle's momentum becomes infinitely large as the speed approaches c. The amount of effort required for each additional increment of velocity becomes larger and larger until no amount of effort can raise the velocity any higher.

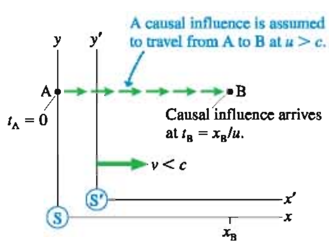
Actually, at a more fundamental level, c is a speed limit for *any* kind of **causal influence.** If I throw a rock and break a window, my throw is the *cause* of the breaking window and the rock is the *causal influence*. If I shoot a laser beam at a light detector that is wired to a firecracker, the light wave is the *causal influence* that leads to the explosion. A causal influence can be any kind of particle, wave, or information that travels from A to B and allows A to be the cause of B.

For two unrelated events—a firecracker explodes in Tokyo and a balloon bursts in Paris—the relativity of simultaneity tells us that they may be simultaneous in one reference frame but not in others. Or in one reference frame the firecracker may explode before the balloon bursts but in some other reference frame the balloon may burst first. These possibilities violate our commonsense view of time, but they're not in conflict with the principle of relativity.

For two causally related events—A *causes* B—it would be nonsense for an experimenter in any reference frame to find that B occurs before A. No experimenter in any reference frame, no matter how it is moving, will find that you are born before your mother is born. If A causes B, then it must be the case that $t_A < t_B$ in *all* reference frames.

Suppose there exists some kind of causal influence that *can* travel at speed $u > c$. **FIGURE 37.35** shows a reference frame S in which event A is at the origin ($x_A = 0$). The faster-than-light causal influence—perhaps some yet-to-be-discovered "z ray"—leaves A at $t_A = 0$ and travels to the point at which it will cause event B. It arrives at x_B at time $t_B = x_B/u$.

FIGURE 37.35 Assume that a causal influence can travel from A to B at a speed $u > c$.



How do events A and B appear in a reference frame S′ that travels at an ordinary speed $v < c$ relative to frame S? We can use the Lorentz transformations to find out.

Because $x_A = 0$ and $t_A = 0$, it's easy to see that $x'_A = 0$ and $t'_A = 0$. That is, the origins of S and S′ overlap at the instant the causal influence leaves event A. More interesting is the time at which this influence reaches B in frame S′. The Lorentz time transformation for event B is

$$t'_B = \gamma\left(t_B - \frac{vx_B}{c^2}\right) = \gamma t_B\left(1 - \frac{v(x_B/t_B)}{c^2}\right) = \gamma t_B\left(1 - \frac{vu}{c^2}\right) \qquad (37.36)$$

where we first factored out t_B, then made use of the fact that $u = x_B/t_B$ in frame S.

We're assuming $u > c$, so let $u = \alpha c$ where $\alpha > 1$ is a constant. Then $vu/c^2 = \alpha v/c$. Now follow the logic:

1. If $v > c/\alpha$, which is possible because $\alpha > 1$, then $vu/c^2 > 1$.
2. If $vu/c^2 > 1$, then the term $(1 - vu/c^2)$ is negative and $t'_B < 0$.
3. If $t'_B < 0$, then event B happens *before* event A in reference frame S′.

In other words, if a causal influence can travel faster than c, then there exist reference frames in which the effect happens before the cause. We know this can't happen, so our assumption $u > c$ must be wrong. **No causal influence of any kind—particle, wave, or yet-to-be-discovered z rays—can travel faster than *c*.**

The existence of a cosmic speed limit is one of the most interesting consequences of the theory of relativity. "Warp drive," in which a spaceship suddenly leaps to faster-than-light velocities, is simply incompatible with the theory of relativity. Rapid travel to the stars will remain in the realm of science fiction unless future scientific discoveries find flaws in Einstein's theory and open the doors to yet-undreamed-of theories. While we can't say with certainty that a scientific theory will never be overturned, there is currently not even a hint of evidence that disagrees with the special theory of relativity.

37.10 Relativistic Energy

Energy is our final topic in this chapter on relativity. Space, time, velocity, and momentum are changed by relativity, so it seems inevitable that we'll need a new view of energy.

In Newtonian mechanics, a particle's kinetic energy $K = \frac{1}{2}mu^2$ can be written in terms of its momentum $p = mu$ as $K = p^2/2m$. This suggests that a relativistic expression for energy will likely involve both the square of p and the particle's mass. We also hope that energy will be conserved in relativity, so a reasonable starting point is with the one quantity we've found that is the same in all inertial reference frames: the spacetime interval s.

Let a particle of mass m move through distance Δx during a time interval Δt, as measured in reference frame S. The spacetime interval is

$$s^2 = c^2(\Delta t)^2 - (\Delta x)^2 = \text{invariant}$$

We can turn this into an expression involving momentum if we multiply by $(m/\Delta\tau)^2$, where $\Delta\tau$ is the proper time (i.e., the time measured by the particle). Doing so gives

$$(mc)^2\left(\frac{\Delta t}{\Delta\tau}\right)^2 - \left(\frac{m\Delta x}{\Delta\tau}\right)^2 = (mc)^2\left(\frac{\Delta t}{\Delta\tau}\right)^2 - p^2 = \text{invariant} \qquad (37.37)$$

where we used $p = m(\Delta x/\Delta\tau)$ from Equation 37.32.

Now Δt, the time interval in frame S, is related to the proper time by the time-dilation result $\Delta t = \gamma_p\Delta\tau$. With this change, Equation 37.37 becomes

$$(\gamma_p mc)^2 - p^2 = \text{invariant}$$

Finally, for reasons that will be clear in a minute, we multiply by c^2, to get

$$(\gamma_p mc^2)^2 - (pc)^2 = \text{invariant} \qquad (37.38)$$

To say that the right side is an *invariant* means it has the same value in all inertial reference frames. We can easily determine the constant by evaluating it in the reference frame in which the particle is at rest. In that frame, where $p = 0$ and $\gamma_p = 1$, we find that

$$(\gamma_p mc^2)^2 - (pc)^2 = (mc^2)^2 \tag{37.39}$$

Let's reflect on what this means before taking the next step. The spacetime interval s has the same value in all inertial reference frames. In other words, $c^2(\Delta t)^2 - (\Delta x)^2 = c^2(\Delta t')^2 - (\Delta x')^2$. Equation 37.39 was derived from the definition of the spacetime interval; hence the quantity mc^2 is also an invariant having the same value in all inertial reference frames. In other words, if experimenters in frames S and S′ both make measurements on this particle of mass m, they will find that

$$(\gamma_p mc^2)^2 - (pc)^2 = (\gamma_p' mc^2)^2 - (p'c)^2 \tag{37.40}$$

Experimenters in different reference frames measure different values for the momentum, but experimenters in all reference frames agree that momentum is a conserved quantity. Equations 37.39 and 37.40 suggest that the quantity $\gamma_p mc^2$ is also an important property of the particle, a property that changes along with p in just the right way to satisfy Equation 37.39. But what is this property?

The first clue comes from checking the units. γ_p is dimensionless and c is a velocity, so $\gamma_p mc^2$ has the same units as the classical expression $\frac{1}{2}mv^2$—namely, units of energy. For a second clue, let's examine how $\gamma_p mc^2$ behaves in the low-velocity limit $u \ll c$. We can use the binomial approximation expression for γ_p to find

$$\gamma_p mc^2 = \frac{mc^2}{\sqrt{1 - u^2/c^2}} \approx \left(1 + \frac{1}{2}\frac{u^2}{c^2}\right)mc^2 = mc^2 + \frac{1}{2}mu^2 \tag{37.41}$$

The second term, $\frac{1}{2}mu^2$, is the low-velocity expression for the kinetic energy K. This is an energy associated with motion. But the first term suggests that the concept of energy is more complex than we originally thought. It appears that **there is an inherent energy associated with mass itself.**

With that as a possibility, subject to experimental verification, let's define the **total energy** E of a particle to be

$$E = \gamma_p mc^2 = E_0 + K = \text{rest energy} + \text{kinetic energy} \tag{37.42}$$

This total energy consists of a **rest energy**

$$E_0 = mc^2 \tag{37.43}$$

and a relativistic expression for the *kinetic energy*

$$K = (\gamma_p - 1)mc^2 = (\gamma_p - 1)E_0 \tag{37.44}$$

This expression for the kinetic energy is very nearly $\frac{1}{2}mu^2$ when $u \ll c$ but, as FIGURE 37.36 shows, differs significantly from the classical value for very high velocities.

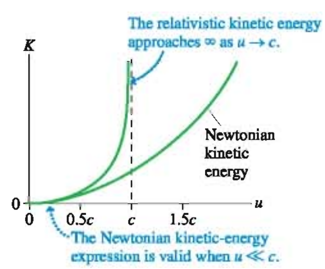


FIGURE 37.36 The relativistic kinetic energy.

Equation 37.43 is, of course, Einstein's famous $E = mc^2$, perhaps the most famous equation in all of physics. Before discussing its significance, we need to tie up some loose ends. First, notice that the right-hand side of Equation 37.39 is the square of the rest energy E_0. Thus we can write a final version of that equation:

$$E^2 - (pc)^2 = E_0^2 \tag{37.45}$$

The quantity E_0 is an *invariant* with the same value mc^2 in *all* inertial reference frames.

Second, notice that we can write

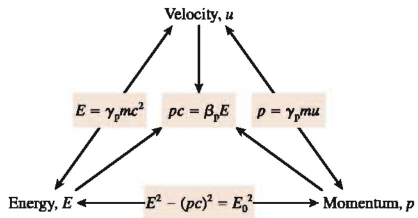
$$pc = (\gamma_p mu)c = \frac{u}{c}(\gamma_p mc^2)$$

But $\gamma_p mc^2$ is the total energy E and $u/c = \beta_p$, where the subscript p, as on γ_p, indicates that we're referring to the motion of a particle within a reference frame, not the motion of two reference frames relative to each other. Thus

$$pc = \beta_p E \tag{37.46}$$

FIGURE 37.37 shows the "velocity-energy-momentum triangle," a convenient way to remember the relationships among the three quantities.

FIGURE 37.37 The velocity-energy-momentum triangle.



EXAMPLE 37.12 Kinetic energy and total energy

Calculate the rest energy and the kinetic energy of (a) a 100 g ball moving with a speed of 100 m/s and (b) an electron with a speed of 0.999c.

MODEL The ball, with $u \ll c$, is a classical particle. We don't need to use the relativistic expression for its kinetic energy. The electron is highly relativistic.

SOLVE a. For the ball, with $m = 0.10$ kg,

$$E_0 = mc^2 = 9.0 \times 10^{15}\ \text{J}$$

$$K = \frac{1}{2}mu^2 = 500\ \text{J}$$

b. For the electron, we start by calculating

$$\gamma_p = \frac{1}{(1 - u^2/c^2)^{1/2}} = 22.4$$

Then, using $m_e = 9.11 \times 10^{-31}$ kg, we find

$$E_0 = mc^2 = 8.2 \times 10^{-14}\ \text{J}$$

$$K = (\gamma_p - 1)E_0 = 170 \times 10^{-14}\ \text{J}$$

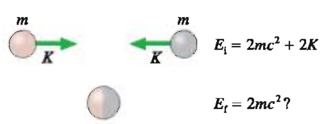
ASSESS The ball's kinetic energy is a typical kinetic energy. Its rest energy, by contrast, is a staggeringly large number. For a relativistic electron, on the other hand, the kinetic energy is more important than the rest energy.

STOP TO THINK 37.8 An electron moves through the lab at 99% the speed of light. The lab reference frame is S and the electron's reference frame is S′. In which reference frame is the electron's rest mass larger?

a. In frame S, the lab frame
b. In frame S′, the electron's frame
c. It is the same in both frames.

Mass-Energy Equivalence

FIGURE 37.38 An inelastic collision between two balls of clay does not seem to conserve the total energy E.



Now we're ready to explore the significance of Einstein's famous equation $E = mc^2$. FIGURE 37.38 shows two balls of clay approaching each other. They have equal masses and equal kinetic energies, and they slam together in a perfectly inelastic collision to form one large ball of clay at rest. In Newtonian mechanics, we would say that the initial energy $2K$ is dissipated by being transformed into an equal amount of thermal energy, raising the temperature of the coalesced ball of clay. But Equation 37.42, $E = E_0 + K$, doesn't say anything about thermal energy. The total energy before the

collision is $E_i = 2mc^2 + 2K$, with the factor of 2 appearing because there are two masses. It seems like the total energy after the collision, when the clay is at rest, should be $2mc^2$, but this value doesn't conserve total energy.

There's ample experimental evidence that energy is conserved, so there must be a flaw in our reasoning. The statement of energy conservation is

$$E_f = Mc^2 = E_i = 2mc^2 + 2K \tag{37.47}$$

where M is the mass of clay after the collision. But, remarkably, this requires

$$M = 2m + \frac{2K}{c^2} \tag{37.48}$$

In other words, **mass is not conserved.** The mass of clay after the collision is larger than the mass of clay before the collision. Total energy can be conserved only if kinetic energy is transformed into an "equivalent" amount of mass.

The mass increase in a collision between two balls of clay is incredibly small, far beyond any scientist's ability to detect. So how do we know if such a crazy idea is true?

FIGURE 37.39 shows an experiment that has been done countless times in the last 50 years at particle accelerators around the world. An electron that has been accelerated to $u \approx c$ is aimed at a target material. When a high-energy electron collides with an atom in the target, it can easily knock one of the electrons out of the atom. Thus we would expect to see two electrons leaving the target: the incident electron and the ejected electron. Instead, *four* particles emerge from the target: three electrons and a positron. A *positron,* or positive electron, is the antimatter version of an electron, identical to an electron in all respects other than having charge $q = +e$.

In chemical-reaction notation, the collision is

$$e^-(\text{fast}) + e^-(\text{at rest}) \rightarrow e^- + e^- + e^- + e^+$$

An electron and a positron have been *created,* apparently out of nothing. Mass $2m_e$ before the collision has become mass $4m_e$ after the collision. (Notice that charge has been conserved in this collision.)

Although the mass has increased, it wasn't created "out of nothing." This is an inelastic collision, just like the collision of the balls of clay, because the kinetic energy after the collision is less than before. In fact, if you measured the energies before and after the collision, you would find that the decrease in kinetic energy is exactly equal to the energy equivalent of the two particles that have been created: $\Delta K = 2m_ec^2$. The new particles have been created *out of energy!*

Particles can be created from energy and particles can return to energy. FIGURE 37.40 shows an electron colliding with a positron, its antimatter partner. When a particle and its antiparticle meet, they *annihilate* each other. The mass disappears, and the energy equivalent of the mass is transformed into two high-energy photons of light. Momentum conservation requires two photons, rather than one, and specifies that the two photons have equal energies and be emitted back to back.

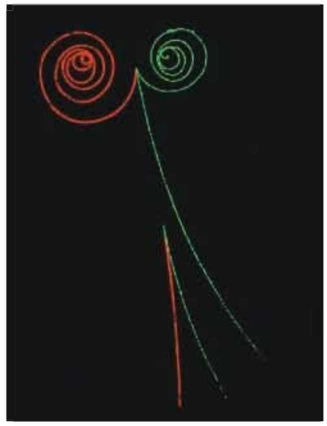
If the electron and positron are fairly slow, so that $K \ll mc^2$, then $E_i \approx E_0 = mc^2$. In that case, energy conservation requires

$$E_f = 2E_{\text{photon}} = E_i \approx 2m_ec^2 \tag{37.49}$$

You learned in Chapter 25 that the energy of a photon of light is $E_{\text{photon}} = hc/\lambda$, where h is Planck's constant. (Photons and their properties will be discussed again in Chapter 39.) Hence the wavelength of the emitted photons is

$$\lambda = \frac{hc}{m_ec^2} \approx 0.0024\ \text{nm} \tag{37.50}$$

This is an extremely short wavelength, even shorter than the wavelengths of x rays. Photons in this wavelength range are called *gamma rays.* And, indeed, the emission of 0.0024 nm gamma rays is observed in many laboratory experiments in which positrons are able to collide with electrons and thus annihilate. In recent years, with the advent of



The tracks of elementary particles in a bubble chamber show the creation of an electron-positron pair. The negative electron and positive positron spiral in opposite directions in the magnetic field.

FIGURE 37.39 An inelastic collision between electrons can create an electron-positron pair.

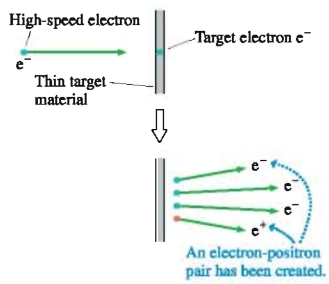


FIGURE 37.40 The annihilation of an electron-positron pair.

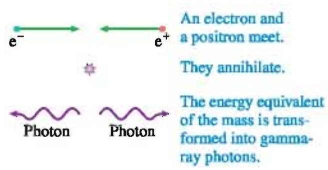
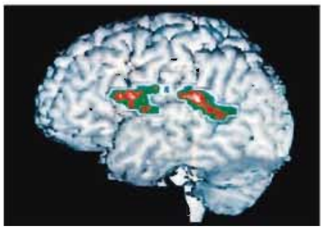




Positron-electron annihilation (a PET scan) provides a noninvasive look into the brain.

gamma-ray telescopes on satellites, astronomers have found 0.0024 nm photons coming from many places in the universe, especially galactic centers—evidence that positrons are abundant throughout the universe.

Positron-electron annihilation is also the basis of the medical procedure known as a positron-emission tomography, or PET scans. A patient ingests a very small amount of a radioactive substance that decays by the emission of positrons. This substance is taken up by certain tissues in the body, especially those tissues with a high metabolic rate. As the substance decays, the positrons immediately collide with electrons, annihilate, and create two gamma-ray photons that are emitted back to back. The gamma rays, which easily leave the body, are detected, and their trajectories are traced backward into the body. The overlap of many such trajectories shows quite clearly the tissue in which the positron emission is occurring. The results are usually shown as false-color photographs, with redder areas indicating regions of higher positron emission.

Conservation of Energy

The creation and annihilation of particles with mass, processes strictly forbidden in Newtonian mechanics, are vivid proof that neither mass nor the Newtonian definition of energy is conserved. Even so, the *total* energy—the kinetic energy *and* the energy equivalent of mass—remains a conserved quantity.

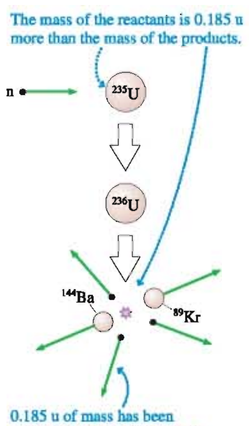
Law of conservation of total energy The energy $E = \sum E_i$ of an isolated system is conserved, where $E_i = (\gamma_p)_i m_i c^2$ is the total energy of particle *i*.

Mass and energy are not the same thing, but, as the last few examples have shown, they are *equivalent* in the sense that mass can be transformed into energy and energy can be transformed into mass as long as the total energy is conserved.

Probably the most well-known application of the conservation of total energy is nuclear fission. The uranium isotope ^{236}U, containing 236 protons and neutrons, does not exist in nature. It can be created when a ^{235}U nucleus absorbs a neutron, increasing its atomic mass from 235 to 236. The ^{236}U nucleus quickly fragments into two smaller nuclei and several extra neutrons, a process known as **nuclear fission.** The nucleus can fragment in several ways, but one is

$$\mathrm{n} + {}^{235}\mathrm{U} \rightarrow {}^{236}\mathrm{U} \rightarrow {}^{144}\mathrm{Ba} + {}^{89}\mathrm{Kr} + 3\mathrm{n}$$

FIGURE 37.41 In nuclear fission, the energy equivalent of lost mass is converted into kinetic energy.



Ba and Kr are the atomic symbols for barium and krypton.

This reaction seems like an ordinary chemical reaction—until you check the masses. The masses of atomic isotopes are known with great precision from many decades of measurement in instruments called mass spectrometers. If you add up the masses on both sides, you find that the mass of the products is 0.185 u smaller than the mass of the initial neutron and ^{235}U, where, you will recall, $1\ \mathrm{u} = 1.66 \times 10^{-27}$ kg is the atomic mass unit. In kilograms the mass loss is 3.07×10^{-28} kg.

Mass has been lost, but the energy equivalent of the mass has not. As FIGURE 37.41 shows, the mass has been converted to kinetic energy, causing the two product nuclei and three neutrons to be ejected at very high speeds. The kinetic energy is easily calculated: $\Delta K = m_{\text{lost}}c^2 = 2.8 \times 10^{-11}$ J.

This is a very tiny amount of energy, but it is the energy released from *one* fission. The number of nuclei in a macroscopic sample of uranium is on the order of N_A, Avogadro's number. Hence the energy available if *all* the nuclei fission is enormous. This energy, of course, is the basis for both nuclear power reactors and nuclear weapons.

We started this chapter with an expectation that relativity would challenge our basic notions of space and time. We end by finding that relativity changes our understanding of mass and energy. Most remarkable of all is that each and every one of these new ideas flows from one simple statement: The laws of physics are the same in all inertial reference frames.

SUMMARY

The goal of Chapter 37 has been to understand how Einstein's theory of relativity changes our concepts of space and time.

General Principles

Principle of Relativity **All the laws of physics are the same in all inertial reference frames.**

- The speed of light c is the same in all inertial reference frames.
- No particle or causal influence can travel at a speed greater than c.

Important Concepts

Space

Spatial measurements depend on the motion of the experimenter relative to the events. An object's length is the difference between *simultaneous* measurements of the positions of both ends.

Proper length ℓ is the length of an object measured in a reference frame in which the object is at rest. The object's length in a frame in which the object moves with velocity v is

$$L = \sqrt{1-\beta^2}\,\ell \le \ell$$

This is called **length contraction.**

Time

Time measurements depend on the motion of the experimenter relative to the events. Events that are simultaneous in reference frame S are not simultaneous in frame S′ moving relative to S.

Proper time $\Delta\tau$ is the time interval between two events measured in a reference frame in which the events occur at the same position. The time interval between the events in a frame moving with relative velocity v is

$$\Delta t = \Delta\tau/\sqrt{1-\beta^2} \ge \Delta\tau$$

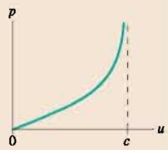
This is called **time dilation.**

Momentum

The law of conservation of momentum is valid in all inertial reference frames if the momentum of a particle with velocity u is $p = \gamma_p m u$, where

$$\gamma_p = 1/\sqrt{1-u^2/c^2}$$

The momentum approaches ∞ as $u \to c$.

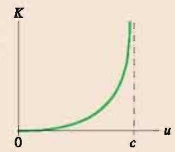


Energy

The law of conservation of energy is valid in all inertial reference frames if the energy of a particle with velocity u is $E = \gamma_p mc^2 = E_0 + K$

Rest energy $E_0 = mc^2$

Kinetic energy $K = (\gamma_p - 1)mc^2$.



Invariants are quantities that have the same value in all inertial reference frames.

Spacetime interval: $s^2 = (c\Delta t)^2 - (\Delta x)^2$

Particle rest energy: $E_0^2 = (mc^2)^2 = E^2 - (pc)^2$

Mass-energy equivalence

Mass m can be transformed into energy $E = mc^2$.

Energy can be transformed into mass $m = \Delta E/c^2$.

Applications

An **event** happens at a specific place in space and time. Spacetime coordinates are (x, t) in frame S and (x', t') in frame S′.

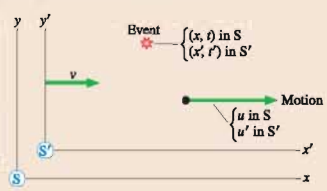
A **reference frame** is a coordinate system with meter sticks and clocks for measuring events. Experimenters at rest relative to each other share the same reference frame.

The **Lorentz transformations** transform spacetime coordinates and velocities between reference frames S and S′.

$$
\begin{aligned}
x' &= \gamma(x - vt) & x &= \gamma(x' + vt')\\
y' &= y & y &= y'\\
z' &= z & z &= z'\\
t' &= \gamma(t - vx/c^2) & t &= \gamma(t' + vx'/c^2)\\
u' &= \frac{u - v}{1 - uv/c^2} & u &= \frac{u' + v}{1 + u'v/c^2}
\end{aligned}
$$

where u and u' are the x- and x'-components of velocity.

$$\beta = \frac{v}{c} \quad \text{and} \quad \gamma = 1/\sqrt{1 - v^2/c^2} = 1/\sqrt{1-\beta^2}$$



Terms and Notation

special relativity	spacetime coordinates, (x, y, z, t)	proper time, $\Delta\tau$	Lorentz transformations
reference frame	synchronized	time dilation	causal influence
inertial reference frame	simultaneous	light year, ly	total energy, E
Galilean principle of relativity	relativity of simultaneity	proper length, ℓ	rest energy, E_0
ether	light clock	length contraction	law of conservation of total energy
principle of relativity	rest frame	invariant	nuclear fission

Problems labeled integrate significant material from earlier chapters.

CONCEPTUAL QUESTIONS

1. FIGURE Q37.1 shows two balls. What are the speed and direction of each (a) in a reference frame that moves with ball 1 and (b) in a reference frame that moves with ball 2?

FIGURE Q37.1

2. Teenagers Sam and Tom are playing chicken in their rockets. As FIGURE Q37.2 shows, an experimenter on earth sees that each is traveling at $0.95c$ as he approaches the other. Sam fires a laser beam toward Tom.
   a. What is the speed of the laser beam relative to Sam?
   b. What is the speed of the laser beam relative to Tom?

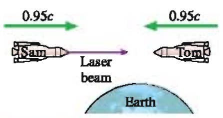

FIGURE Q37.2

3. Firecracker A is 300 m from you. Firecracker B is 600 m from you in the same direction. You see both explode at the same time. Define event 1 to be "firecracker A explodes" and event 2 to be "firecracker B explodes." Does event 1 occur before, after, or at the same time as event 2? Explain.
4. Firecrackers A and B are 600 m apart. You are standing exactly halfway between them. Your lab partner is 300 m on the other side of firecracker A. You see two flashes of light, from the two explosions, at exactly the same instant of time. Define event 1 to be "firecracker A explodes" and event 2 to be "firecracker B explodes." According to your lab partner, based on measurements he or she makes, does event 1 occur before, after, or at the same time as event 2? Explain.
5. FIGURE Q37.5 shows Peggy standing at the center of her railroad car as it passes Ryan on the ground. Firecrackers attached to the ends of the car explode. A short time later, the flashes from the two explosions arrive at Peggy at the same time.
   a. Were the explosions simultaneous in Peggy's reference frame? If not, which exploded first? Explain.
   b. Were the explosions simultaneous in Ryan's reference frame? If not, which exploded first? Explain.

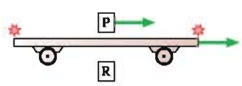

FIGURE Q37.5

6. FIGURE Q37.6 shows a rocket traveling from left to right. At the instant it is halfway between two trees, lightning simultaneously (in the rocket's frame) hits both trees.
   a. Do the light flashes reach the rocket pilot simultaneously? If not, which reaches her first? Explain.
   b. A student was sitting on the ground halfway between the trees as the rocket passed overhead. According to the student, were the lightning strikes simultaneous? If not, which tree was hit first? Explain.

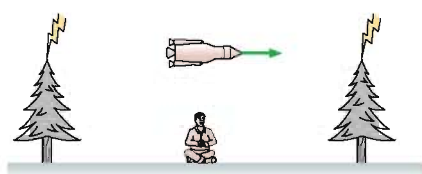

FIGURE Q37.6

7. Your friend flies from Los Angeles to New York. She carries an accurate stopwatch with her to measure the flight time. You and your assistants on the ground also measure the flight time.
   a. Identify the two events associated with this measurement.
   b. Who, if anyone, measures the proper time?
   c. Who, if anyone, measures the shorter flight time?
8. As the meter stick in FIGURE Q37.8 flies past you, you simultaneously measure the positions of both ends and determine that $L < 1$ m.
   a. To an experimenter in frame S′, the meter stick's frame, did you make your two measurements simultaneously? If not, which end did you measure first? Explain.
   b. Can experimenters in frame S′ give an explanation for why your measurement is less than 1 m?

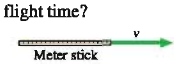

FIGURE Q37.8

9. A 100-m-long train is heading for an 80-m-long tunnel. If the train moves sufficiently fast, is it possible, according to experimenters on the ground, for the entire train to be inside the tunnel at one instant of time? Explain.

10. Particle A has half the mass and twice the speed of particle B. Is the momentum p_A less than, greater than, or equal to p_B? Explain.

11. Event A occurs at spacetime coordinates (300 m, 2 μs).
  a. Event B occurs at spacetime coordinates (1200 m, 6 μs). Could A possibly be the cause of B? Explain.
  b. Event C occurs at spacetime coordinates (2400 m, 8 μs). Could A possibly be the cause of C? Explain.

EXERCISES AND PROBLEMS

Exercises

Section 37.2 Galilean Relativity

1. | At $t = 1.0$ s, a firecracker explodes at $x = 10$ m in reference frame S. Four seconds later, a second firecracker explodes at $x = 20$ m. Reference frame S′ moves in the x-direction at a speed of 5.0 m/s. What are the positions and times of these two events in frame S′?
2. || A firecracker explodes in reference frame S at $t = 1.0$ s. A second firecracker explodes at the same position at $t = 3.0$ s. In reference frame S′, which moves in the x-direction at speed v, the first explosion is detected at $x' = 4.0$ m and the second at $x' = -4.0$ m.
  a. What is the speed of frame S′ relative to frame S?
  b. What is the position of the two explosions in frame S?
3. | A sprinter crosses the finish line of a race. The roar of the crowd in front approaches her at a speed of 360 m/s. The roar from the crowd behind her approaches at 330 m/s. What are the speed of sound and the speed of the sprinter?
4. | A baseball pitcher can throw a ball with a speed of 40 m/s. He is in the back of a pickup truck that is driving away from you. He throws the ball in your direction, and it floats toward you at a lazy 10 m/s. What is the speed of the truck?
5. | A newspaper delivery boy is riding his bicycle down the street at 5.0 m/s. He can throw a paper at a speed of 8.0 m/s. What is the paper's speed relative to the ground if he throws the paper (a) forward, (b) backward, and (c) to the side?

Section 37.3 Einstein's Principle of Relativity

6. | An out-of-control alien spacecraft is diving into a star at a speed of 1.0×10^8 m/s. At what speed, relative to the spacecraft, is the starlight approaching?
7. | A starship blasts past the earth at 2.0×10^8 m/s. Just after passing the earth, it fires a laser beam out the back of the starship. With what speed does the laser beam approach the earth?
8. | A positron moving in the positive x-direction at 2.0×10^8 m/s collides with an electron at rest. The positron and electron annihilate, producing two gamma-ray photons. Photon 1 travels in the positive x-direction and photon 2 travels in the negative x-direction. What is the speed of each photon?

Section 37.4 Events and Measurements

Section 37.5 The Relativity of Simultaneity

9. | Your job is to synchronize the clocks in a reference frame. You are going to do so by flashing a light at the origin at $t = 0$ s. To what time should the clock at $(x, y, z) = (30\text{ m}, 40\text{ m}, 0\text{ m})$ be preset?
10. | Bjorn is standing at $x = 600$ m. Firecracker 1 explodes at the origin and firecracker 2 explodes at $x = 900$ m. The flashes from both explosions reach Bjorn's eye at $t = 3.0$ μs. At what time did each firecracker explode?
11. || Bianca is standing at $x = 600$ m. Firecracker 1, at the origin, and firecracker 2, at $x = 900$ m, explode simultaneously. The flash from firecracker 1 reaches Bianca's eye at $t = 3.0$ μs. At what time does she see the flash from firecracker 2?
12. || You are standing at $x = 9.0$ km. Lightning bolt 1 strikes at $x = 0$ km and lightning bolt 2 strikes at $x = 12.0$ km. Both flashes reach your eye at the same time. Your assistant is standing at $x = 3.0$ km. Does your assistant see the flashes at the same time? If not, which does she see first and what is the time difference between the two?
13. || You are standing at $x = 9.0$ km and your assistant is standing at $x = 3.0$ km. Lightning bolt 1 strikes at $x = 0$ km and lightning bolt 2 strikes at $x = 12.0$ km. You see the flash from bolt 2 at $t = 10$ μs and the flash from bolt 1 at $t = 50$ μs. According to your assistant, were the lightning strikes simultaneous? If not, which occurred first and what was the time difference between the two?
14. || Jose is looking to the east. Lightning bolt 1 strikes a tree 300 m from him. Lightning bolt 2 strikes a barn 900 m from him in the same direction. Jose sees the tree strike 1.0 μs before he sees the barn strike. According to Jose, were the lightning strikes simultaneous? If not, which occurred first and what was the time difference between the two?
15. || You are flying your personal rocketcraft at 0.9c from Star A toward Star B. The distance between the stars, in the stars' reference frame, is 1.0 ly. Both stars happen to explode simultaneously in your reference frame at the instant you are exactly halfway between them. Do you see the flashes simultaneously? If not, which do you see first and what is the time difference between the two?

Section 37.6 Time Dilation

16. || A cosmic ray travels 60 km through the earth's atmosphere in 400 μs, as measured by experimenters on the ground. How long does the journey take according to the cosmic ray?
17. || At what speed, as a fraction of c, does a moving clock tick at half the rate of an identical clock at rest?
18. || An astronaut travels to a star system 4.5 ly away at a speed of 0.9c. Assume that the time needed to accelerate and decelerate is negligible.
  a. How long does the journey take according to Mission Control on earth?
  b. How long does the journey take according to the astronaut?
  c. How much time elapses between the launch and the arrival of the first radio message from the astronaut saying that she has arrived?

19. ‖ a. How fast must a rocket travel on a journey to and from a distant star so that the astronauts age 10 years while the Mission Control workers on earth age 120 years?
    b. As measured by Mission Control, how far away is the distant star?
20. ‖ You fly 5000 km across the United States on an airliner at 250 m/s. You return two days later at the same speed.
    a. Have you aged more or less than your friends at home?
    b. By how much?
    Hint: Use the binomial approximation.
21. ‖ At what speed, in m/s, would a moving clock lose 1.0 ns in 1.0 day according to experimenters on the ground?
    Hint: Use the binomial approximation.

Section 37.7 Length Contraction

22. | At what speed, as a fraction of c, will a moving rod have a length 60% that of an identical rod at rest?
23. | Jill claims that her new rocket is 100 m long. As she flies past your house, you measure the rocket's length and find that it is only 80 m. Should Jill be cited for exceeding the $0.5c$ speed limit?
24. ‖ A muon travels 60 km through the atmosphere at a speed of $0.9997c$. According to the muon, how thick is the atmosphere?
25. | A cube has a density of 2000 kg/m^3 while at rest in the laboratory. What is the cube's density as measured by an experimenter in the laboratory as the cube moves through the laboratory at 90% of the speed of light in a direction perpendicular to one of its faces?
26. | Our Milky Way galaxy is 100,000 ly in diameter. A spaceship crossing the galaxy measures the galaxy's diameter to be a mere 1.0 ly.
    a. What is the speed of the spaceship relative to the galaxy?
    b. How long is the crossing time as measured in the galaxy's reference frame?
27. | A human hair is about 50 μm in diameter. At what speed, in m/s, would a meter stick "shrink by a hair"?
    Hint: Use the binomial approximation.

Section 37.8 The Lorentz Transformations

28. | An event has spacetime coordinates $(x, t) = (1200\text{ m}, 2.0\ \mu\text{s})$ in reference frame S. What are the event's spacetime coordinates (a) in reference frame S′ that moves in the positive x-direction at $0.8c$ and (b) in reference frame S″ that moves in the negative x-direction at $0.8c$?
29. ‖ A rocket travels in the x-direction at speed $0.6c$ with respect to the earth. An experimenter on the rocket observes a collision between two comets and determines that the spacetime coordinates of the collision are $(x', t') = (3.0 \times 10^{10}\text{ m}, 200\text{ s})$. What are the spacetime coordinates of the collision in earth's reference frame?
30. ‖ In the earth's reference frame, a tree is at the origin and a pole is at $x = 30$ km. Lightning strikes both the tree and the pole at $t = 10\ \mu$s. The lightning strikes are observed by a rocket traveling in the x-direction at $0.5c$.
    a. What are the spacetime coordinates for these two events in the rocket's reference frame?
    b. Are the events simultaneous in the rocket's frame? If not, which occurs first?
31. ‖ A rocket cruising past earth at $0.8c$ shoots a bullet out the back door, opposite the rocket's motion, at $0.9c$ relative to the rocket. What is the bullet's speed relative to the earth?
32. ‖ A laboratory experiment shoots an electron to the left at $0.9c$. What is the electron's speed relative to a proton moving to the right at $0.9c$?
33. ‖ A distant quasar is found to be moving away from the earth at $0.8c$. A galaxy closer to the earth and along the same line of sight is moving away from us at $0.2c$. What is the recessional speed of the quasar as measured by astronomers in the other galaxy?

Section 37.9 Relativistic Momentum

34. ‖ A proton is accelerated to $0.999c$.
    a. What is the proton's momentum?
    b. By what factor does the proton's momentum exceed its Newtonian momentum?
35. | A 1.0 g particle has momentum 400,000 kg m/s. What is the particle's speed?
36. ‖ At what speed is a particle's momentum twice its Newtonian value?
37. ‖ What is the speed of a particle whose momentum is mc?

Section 37.10 Relativistic Energy

38. ‖ What are the kinetic energy, the rest energy, and the total energy of a 1.0 g particle with a speed of $0.8c$?
39. | A quarter-pound hamburger with all the fixings has a mass of 200 g. The food energy of the hamburger (480 food calories) is 2 MJ.
    a. What is the energy equivalent of the mass of the hamburger?
    b. By what factor does the energy equivalent exceed the food energy?
40. | How fast must an electron move so that its total energy is 10% more than its rest mass energy?
41. ‖ At what speed is a particle's kinetic energy twice its rest energy?
42. ‖ At what speed is a particle's total energy twice its rest energy?

Problems

43. | A 50 g ball moving to the right at 4.0 m/s overtakes and collides with a 100 g ball moving to the right at 2.0 m/s. The collision is perfectly elastic. Use reference frames and the Chapter 10 result for perfectly elastic collisions to find the speed and direction of each ball after the collision.
44. | A 300 g ball moving to the right at 2.0 m/s has a perfectly elastic collision with a 100 g ball moving to the left at 8.0 m/s. Use reference frames and the Chapter 10 result for perfectly elastic collisions to find the speed and direction of each ball after the collision.
45. ‖ A billiard ball has a perfectly elastic collision with a second billiard ball of equal mass. Afterward, the first ball moves to the left at 2.0 m/s and the second to the right at 4.0 m/s. Use reference frames and the Chapter 10 result for perfectly elastic collisions to find the speed and direction of each ball before the collision.
46. | A 9.0 kg artillery shell is moving to the right at 100 m/s when suddenly it explodes into two fragments, one twice as heavy as the other. Measurements reveal that 900 J of energy are released in the explosion and that the heavier fragment is in front of the lighter fragment. Find the velocity of each fragment relative to the ground by analyzing the explosion in the reference frame of (a) the ground and (b) the shell. (c) Is the problem easier to solve in one reference frame?

47. || The diameter of the solar system is 10 light hours. A spaceship crosses the solar system in 15 hours, as measured on earth. How long, in hours, does the passage take according to passengers on the spaceship?
Hint: $c = 1$ light hour per hour.

48. || A 30-m-long rocket train car is traveling from Los Angeles to New York at $0.5c$ when a light at the center of the car flashes. When the light reaches the front of the car, it immediately rings a bell. Light reaching the back of the car immediately sounds a siren.
  a. Are the bell and siren simultaneous events for a passenger seated in the car? If not, which occurs first and by how much time?
  b. Are the bell and siren simultaneous events for a bicyclist waiting to cross the tracks? If not, which occurs first and by how much time?

49. || The star Alpha goes supernova. Ten years later and 100 ly away, as measured by astronomers in the galaxy, star Beta explodes.
  a. Is it possible that the explosion of Alpha is in any way responsible for the explosion of Beta? Explain.
  b. An alien spacecraft passing through the galaxy finds that the distance between the two explosions is 120 ly. According to the aliens, what is the time between the explosions?

50. || Two events in reference frame S occur 10 μs apart at the same point in space. The distance between the two events is 2400 m in reference frame S′.
  a. What is the time interval between the events in reference frame S′?
  b. What is the velocity of S′ relative to S?

51. ||| A starship voyages to a distant planet 10 ly away. The explorers stay 1 yr, return at the same speed, and arrive back on earth 26 yr after they left. Assume that the time needed to accelerate and decelerate is negligible.
  a. What is the speed of the starship?
  b. How much time has elapsed on the astronauts' chronometers?

52. || In Section 37.6 we saw that muons can reach the ground because of time dilation. But how do things appear in the muon's reference frame, where the muon's half-life is only 1.5 μs? How can a muon travel the 60 km to reach the earth's surface before decaying? Resolve this apparent paradox. Be as quantitative as you can in your answer.

53. || The Stanford Linear Accelerator (SLAC) accelerates electrons to $c = 0.99999997c$ in a 3.2-km-long tube. If they travel the length of the tube at full speed (they don't, because they are accelerating), how long is the tube in the electrons' reference frame?

54. || In an attempt to reduce the extraordinarily long travel times for voyaging to distant stars, some people have suggested traveling at close to the speed of light. Suppose you wish to visit the red giant star Betelgeuse, which is 430 ly away, and that you want your 20,000 kg rocket to move so fast that you age only 20 years during the round trip.
  a. How fast must the rocket travel relative to earth?
  b. How much energy is needed to accelerate the rocket to this speed?
  c. Compare this amount of energy to the total energy used by the United States in the year 2005, which was roughly 1.0×10^{20} J.

55. | A rocket traveling at $0.5c$ sets out for the nearest star, Alpha Centauri, which is 4.25 ly away from earth. It will return to earth immediately after reaching Alpha Centauri. What distance will the rocket travel and how long will the journey last according to (a) stay-at-home earthlings and (b) the rocket crew? (c) Which answers are the correct ones, those in part a or those in part b?

56. || The star Delta goes supernova. One year later and 2 ly away, as measured by astronomers in the galaxy, star Epsilon explodes. Let the explosion of Delta be at $x_D = 0$ and $t_D = 0$. The explosions are observed by three spaceships cruising through the galaxy in the direction from Delta to Epsilon at velocities $v_1 = 0.3c$, $v_2 = 0.5c$, and $v_3 = 0.7c$.
  a. What are the times of the two explosions as measured by scientists on each of the three spaceships?
  b. Does one spaceship find that the explosions are simultaneous? If so, which one?
  c. Does one spaceship find that Epsilon explodes before Delta? If so, which one?
  d. Do your answers to parts b and c violate the idea of causality? Explain.

57. || Two rockets approach each other. Each is traveling at $0.75c$ in the earth's reference frame. What is the speed of one rocket relative to the other?

58. || A rocket fires a projectile at a speed of $0.95c$ while traveling past the earth. An earthbound scientist measures the projectile's speed to be $0.90c$. What was the rocket's speed?

59. || Through what potential difference must an electron be accelerated, starting from rest, to acquire a speed of $0.99c$?

60. || What is the speed of a proton after being accelerated from rest through a 50×10^6 V potential difference?

61. || The half-life of a muon at rest is 1.5 μs. Muons that have been accelerated to a very high speed and are then held in a circular storage ring have a half-life of 7.5 μs.
  a. What is the speed of the muons in the storage ring?
  b. What is the total energy of a muon in the storage ring? The mass of a muon is 207 times the mass of an electron.

62. || A solar flare blowing out from the sun at $0.9c$ is overtaking a rocket as it flies away from the sun at $0.8c$. According to the crew on board, with what speed is the flare gaining on the rocket?

63. || This chapter has assumed that lengths perpendicular to the direction of motion are not affected by the motion. That is, motion in the x-direction does not cause length contraction along the y- or z-axes. To find out if this is really true, consider two spray-paint nozzles attached to rods perpendicular to the x-axis. It has been confirmed that, when both rods are at rest, both nozzles are exactly 1 m above the base of the rod. One rod is placed in the S reference frame with its base on the x-axis; the other is placed in the S′ reference frame with its base on the x'-axis. The rods then swoop past each other and, as FIGURE P37.63 shows, each paints a stripe across the other rod.

We will use proof by contradiction. Assume that objects perpendicular to the motion *are* contracted. An experimenter in frame S finds that the S′ nozzle, as it goes past, is less than 1 m above the x-axis. The principle of relativity says that an experiment carried out in two different inertial reference frames will have the same outcome in both.
  a. Pursue this line of reasoning and show that you end up with a logical contradiction, two mutually incompatible situations.
  b. What can you conclude from this contradiction?

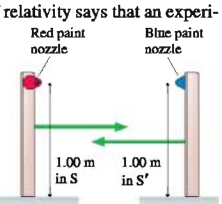

FIGURE P37.63

64. || Derive the Lorentz transformations for t and t'.
Hint: See the comment following Equation 37.22.

65. || a. Derive a velocity transformation equation for u_y and u_y'. Assume that the reference frames are in the standard orientation with motion parallel to the x- and x'-axes.
b. A rocket passes the earth at $0.8c$. As it goes by, it launches a projectile at $0.6c$ perpendicular to the direction of motion. What is the projectile's speed in the earth's reference frame?

66. | What is the momentum of a particle with speed $0.95c$ and total energy 2.0×10^{-10} J?

67. || What is the momentum of a particle whose total energy is four times its rest energy? Give your answer as a multiple of mc.

68. || a. What are the momentum and total energy of a proton with speed $0.99c$?
b. What is the proton's momentum in a different reference frame in which $E' = 5.0 \times 10^{-10}$ J?

69. || At what speed is the kinetic energy of a particle twice its Newtonian value?

70. || What is the speed of an electron whose total energy equals the rest mass of a proton?

71. || A typical nuclear power plant generates electricity at the rate of 1000 MW. The efficiency of transforming thermal energy into electrical energy is $\frac{1}{3}$ and the plant runs at full capacity for 80% of the year. (Nuclear power plants are down about 20% of the time for maintenance and refueling.)
a. How much thermal energy does the plant generate in one year?
b. What mass of uranium is transformed into energy in one year?

72. || The sun radiates energy at the rate 3.8×10^{26} W. The source of this energy is fusion, a nuclear reaction in which mass is transformed into energy. The mass of the sun is 2.0×10^{30} kg.
a. How much mass does the sun lose each year?
b. What percent is this of the sun's total mass?
c. Estimate the lifetime of the sun.

73. || The radioactive element radium (Ra) decays by a process known as *alpha decay*, in which the nucleus emits a helium nucleus. (These high-speed helium nuclei were named alpha particles when radioactivity was first discovered, long before the identity of the particles was established.) The reaction is $^{226}\text{Ra} \rightarrow {}^{222}\text{Rn} + {}^{4}\text{He}$, where Rn is the element radon. The accurately measured atomic masses of the three atoms are 226.025, 222.017, and 4.003. How much energy is released in each decay? (The energy released in radioactive decay is what makes nuclear waste "hot.")

74. || The nuclear reaction that powers the sun is the fusion of four protons into a helium nucleus. The process involves several steps, but the net reaction is simply $4\text{p} \rightarrow {}^{4}\text{He} + \text{energy}$. The mass of a helium nucleus is known to be 6.64×10^{-27} kg.
a. How much energy is released in each fusion?
b. What fraction of the initial rest mass energy is this energy?

75. || An electron moving to the right at $0.9c$ collides with a positron moving to the left at $0.9c$. The two particles annihilate and produce two gamma-ray photons. What is the wavelength of the photons?

76. || Section 37.10 looked at the inelastic collision $e^-(\text{fast}) + e^-(\text{at rest}) \rightarrow e^- + e^- + e^- + e^+$.
a. What is the threshold kinetic energy of the fast electron? That is, what minimum kinetic energy must the electron have to allow this process to occur?
b. What is the speed of an electron with the threshold kinetic energy?

Challenge Problems

77. Two rockets, A and B, approach the earth from opposite directions at speed $0.8c$. The length of each rocket measured in its rest frame is 100 m. What is the length of rocket A as measured by the crew of rocket B?

78. Two rockets are each 1000 m long in their rest frame. Rocket Orion, traveling at $0.8c$ relative to the earth, is overtaking rocket Sirius, which is poking along at a mere $0.6c$. According to the crew on Sirius, how long does Orion take to completely pass? That is, how long is it from the instant the nose of Orion is at the tail of Sirius until the tail of Orion is at the nose of Sirius?

79. Some particle accelerators allow protons (p^+) and antiprotons (p^-) to circulate at equal speeds in opposite directions in a device called a *storage ring*. The particle beams cross each other at various points to cause $\text{p}^+ + \text{p}^-$ collisions. In one collision, the outcome is $\text{p}^+ + \text{p}^- \rightarrow e^+ + e^- + \gamma + \gamma$, where γ represents a high-energy gamma-ray photon. The electron and positron are ejected from the collision at $0.9999995c$ and the gamma-ray photon wavelengths are found to be 1.0×10^{-6} nm. What were the proton and antiproton speeds prior to the collision?

80. The rockets of the Goths and the Huns are each 1000 m long in their rest frame. The rockets pass each other, virtually touching, at a relative speed of $0.8c$. The Huns have a laser cannon at the rear of their rocket that shoots a deadly laser beam at right angles to the motion. The captain of the Hun rocket wants to send a threatening message to the Goths by "firing a shot across their bow." He tells his first mate, "The Goths' rocket is length contracted to 600 m. Fire the laser cannon at the instant the nose of our rocket passes the tail of their rocket. The laser beam will cross 400 m in front of them." But things are different in the Goths' reference frame. The Goth captain muses, "The Huns' rocket is length contracted to 600 m, 400 m shorter than our rocket. If they fire the laser cannon as their nose passes the tail of our rocket, the lethal laser blast will go right through our side."

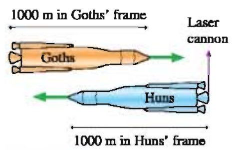

FIGURE CP37.80

The first mate on the Hun rocket fires as ordered. Does the laser beam blast the Goths or not? Resolve this paradox. Show that, when properly analyzed, the Goths and the Huns agree on the outcome. Your analysis should contain both quantitative calculations and written explanation.

81. A very fast pole vaulter lives in the country. One day, while practicing, he notices a 10.0-m-long barn with the doors open at both ends. He decides to run through the barn at $0.866c$ while carrying his 16.0-m-long pole. The farmer, who sees him coming, says. "Aha! This guy's pole is length contracted to 8.0 m. There will be a short interval of time when the pole is entirely inside the barn. If I'm quick, I can simultaneously close both barn doors while the pole vaulter and his pole are inside." The pole vaulter, who sees the farmer beside the barn, thinks to himself, "That farmer is crazy. The barn is length contracted and is only 5.0 m long. My 16.0-m-long pole cannot fit into a 5.0-m-long barn. If the farmer closes the doors just as the tip of my pole reaches the back door, the front door will break off the last 11.0 m of my pole."

Can the farmer close the doors without breaking the pole? Show that, when properly analyzed, the farmer and the pole vaulter agree on the outcome. Your analysis should contain both quantitative calculations and written explanation. It's obvious that the pole vaulter cannot stop quickly, so you can assume that the doors are paper thin and that the pole breaks through without slowing down.

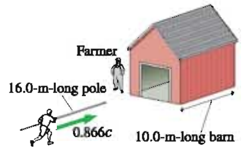

FIGURE CP37.81

STOP TO THINK ANSWERS

Stop to Think 37.1: a, c, and f. These move at constant velocity, or very nearly so. The others are accelerating.

Stop to Think 37.2: a. $u' = u - v = -10\text{ m/s} - 6\text{ m/s} = -16\text{ m/s}$. The *speed* is 16 m/s.

Stop to Think 37.3: c. Even the light has a slight travel time. The event is the hammer hitting the nail, not your seeing the hammer hit the nail.

Stop to Think 37.4: At the same time. Mark is halfway between the tree and the pole, so the fact that he *sees* the lightning bolts at the same time means they *happened* at the same time. It's true that Nancy *sees* event 1 before event 2, but the events actually occurred before she sees them. Mark and Nancy share a reference frame, because they are at rest relative to each other, and all experimenters in a reference frame, after correcting for any signal delays, *agree* on the spacetime coordinates of an event.

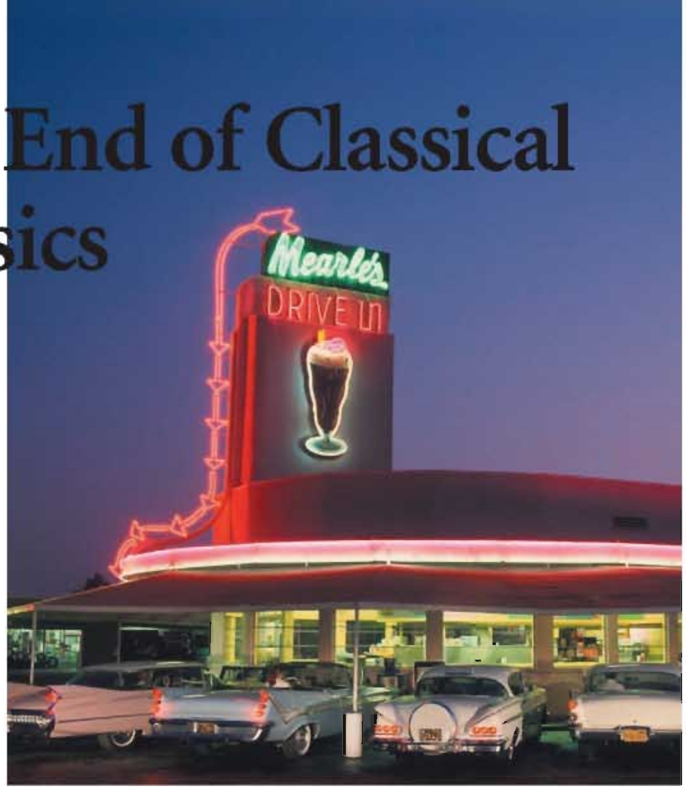
Stop to Think 37.5: After. This is the same as the case of Peggy and Ryan. In Mark's reference frame, as in Ryan's, the events are simultaneous. Nancy *sees* event 1 first, but the time when an event is seen is not when the event actually happens. Because all experimenters in a reference frame agree on the spacetime coordinates of an event, Nancy's position in her reference frame cannot affect the order of the events. If Nancy had been passing Mark at the instant the lightning strikes occur in Mark's frame, then Nancy would be equivalent to Peggy. Event 2, like the firecracker at the front of Peggy's railroad car, occurs first in Nancy's reference frame.

Stop to Think 37.6: c. Nick measures proper time because Nick's clock is present at both the "nose passes Nick" event and the "tail passes Nick" event. Proper time is the smallest measured time interval between two events.

Stop to Think 37.7: $L_A > L_B = L_C$. Anjay measures the pole's proper length because it is at rest in his reference frame. Proper length is the longest measured length. Beth and Charles may *see* the pole differently, but they share the same reference frame and their *measurements* of the length agree.

Stop to Think 37.8: c. The rest energy E_0 is an invariant, the same in all inertial reference frames. Thus $m = E_0/c^2$ is independent of speed.

38 The End of Classical Physics



Studies of the light emitted by gas discharge tubes helped bring classical physics to an end.

▶ Looking Ahead

The goal of Chapter 38 is to understand how scientists discovered the properties of atoms and how these discoveries led to the need for a new theory of light and matter. In this chapter you will learn:

- How the electron was discovered and its charge measured.
- How the nucleus was discovered and its properties identified.
- How to use Rutherford's nuclear model of the atom.
- How atoms emit and absorb light.

◀ Looking Back

The material in this chapter depends on many ideas from classical physics. Please review:

- Section 16.2 Atomic masses and the atomic mass number.
- Sections 22.3 and 25.1 Diffraction gratings and spectroscopy.
- Sections 29.2 and 29.6 Electric potential and potential energy.
- Section 33.7 Charged particles in magnetic fields.

Except for relativity and a brief preview of quantum physics in Chapter 25, everything we have studied until now was known by 1900. Newtonian mechanics, thermodynamics, and Maxwell's theory of electromagnetism form what we call *classical physics.* It is an impressive body of knowledge, with immense explanatory power. Many scientists of the late 1800s felt that they could use these theories to explain just about anything, and some felt there was nothing left to discover.

But within the span of just a few years, right around 1900, investigations into the structure of matter led to many astonishing discoveries that were at odds with classical physics. Discoveries that defied explanation came from investigations as simple as measuring the spectrum of light emitted by gas discharge tubes. It was soon recognized that the laws of classical physics break down when applied to atomic systems. Physicists in the early years of the 20th century had to reexamine their most basic assumptions about the nature of matter and light.

Our goal in this chapter is twofold. The first is to learn how scientists in the 19th and early 20th centuries discovered the properties of atoms. Michael Faraday noted long ago that it is "easy to talk of atoms" but quite another thing to have real knowledge of atoms. We cannot see atoms, so what is the *evidence* that leads us to our current understanding of the atomic theory of matter?

Our second goal is to recognize that many of the newly found atomic properties could not be reconciled with classical physics. Before we launch into quantum physics, it is important to recognize where classical physics failed and why a new theory of light and matter was needed.

38.1 Physics in the 1800s

Scientists in 1800 had three major realms of inquiry: matter, electricity, and light.

Matter

The idea that matter consists of small, indivisible particles can be traced back to Leucippus and his student Democritus, who flourished in ancient Greece around 440–420 BCE. They called these particles *atoms,* Greek for "not divisible." Atomism was not widely accepted, due in no little part to the complete lack of evidence for atoms, but atomic ideas did manage to maintain a minority status throughout the Middle Ages. Then, at about the time of Newton and the beginnings of a mechanistic conception of the world, interest in atoms revived.

Newton noted that Boyle's law of gases—the fact that pV remains constant for an isothermal process—could be explained if a gas consisted of particles. In 1738, Daniel Bernoulli advanced the idea that gases are composed of small, atom-like particles in random motion. However, the *evidence* for atoms was still far too weak for Bernoulli's ideas to be more than a curiosity.

Things began to change in the early years of the 19th century. The English chemist John Dalton argued that much of what was known about chemical reactions could be understood if all matter of a particular chemical element consisted of identical, indestructible atoms. The unique feature of Dalton's work, which made it more science than speculation, was his attempt to determine the relative masses of the atoms of different elements. These ideas were extended by the Italian chemist Amedeo Avogadro, who postulated that atoms could stick together to form more complex entities he called *molecules* and that equal volumes of gases at equal temperatures contain equal numbers of molecules.

The evidence for atoms grew stronger as thermodynamics and the kinetic theory of gases developed in the mid-19th century. Slight deviations from the ideal-gas law at high pressures, which could be understood if the atoms were beginning to come into close proximity to one another, led to a rough estimate of atomic sizes. The existence of atoms with diameters of approximately 10^{-10} m was widely accepted by 1890.

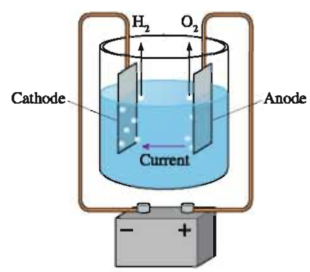
Electricity

The generation of static electricity by rubbing amber with fur had been known since antiquity, but the discovery of electric currents in around 1800 raised interesting new questions. For example, is the "electric substance" a continuous fluid or does it consist of granular particles of electricity? There was no direct evidence, but the flow of current suggested a fluid of some sort. This supposition was analogous to the prevailing belief that heat was a fluid called *caloric.*

It took only two months from Volta's invention in 1800 of the battery until the discovery that an electric current through water decomposes the water into hydrogen and oxygen, a process called **electrolysis.** The basic experiment, done today in chemistry classes, is shown in FIGURE 38.1. The positive and negative terminals of a battery are connected to pieces of metal called *electrodes*. The negative electrode is called the *cathode* and the positive one is the *anode.* Bubbles of gas appear at the electrodes—hydrogen at one and oxygen at the other—and can be collected in tubes.

The outcome of this experiment does not surprise us today, but at the time of its first performance water had long been regarded as one of the basic elements. The decomposition of water forced scientists to reconsider the basic building blocks of matter. Furthermore, these newly discovered effects suggested a previously unsuspected connection between electricity and matter.

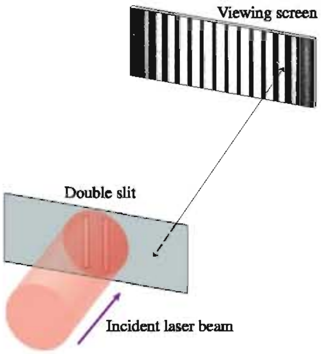
FIGURE 38.1 A current through water decomposes it into hydrogen and oxygen.



Light

The question What is light? had long been debated. Newton, as we have noted, favored a *corpuscular* theory whereby small particles of light travel in straight lines. His conviction was based largely on the sharp shadows cast by sunlight, in contrast to the diffraction of water waves as they pass barriers. Newton's view was dominant throughout the 18th century.

FIGURE 38.2 Young's double-slit experiment showed that light is a wave.



The situation changed quickly as the 19th century opened. In 1801, the English linguist, physician, and scientist Thomas Young demonstrated the interference of light with his celebrated double-slit experiment, shown in FIGURE 38.2. The wave model of light was given a more rigorous mathematical foundation in 1818 by the French physicist Augustin Fresnel. Fresnel's theory predicted a number of diffraction effects that had not been previously observed. These predicted effects were initially criticized as being contrary to common sense, but their subsequent experimental verification validated the wave model of light.

But if light is a wave, what is waving? What is the medium? How can light travel through a vacuum? The corpuscular theory had not faced these difficulties, but they were brought to the forefront by the evidence that light must be some kind of wave.

38.2 Faraday

The three lines of inquiry—matter, electricity, and light—came together during the 1820s in the person of Michael Faraday, one of the most remarkable scientific geniuses in history. Faraday conducted three investigations of particular interest to us.

Electrical Conduction in Liquids

Others had already begun to study electrolysis, but it was Faraday's systematic and careful measurements that revealed the laws governing electrolysis. Faraday showed that electrolysis is most easily understood on the basis of an atomic theory of matter, and he found that there is a *charge* associated with each atom in the solution. Today these charges are called positive and negative *ions.*

In fuel cells, which will power cars in the near future, oxygen and hydrogen are combined to produce water and an electric current. This is the reverse of the electrolysis process shown in Figure 38.1.

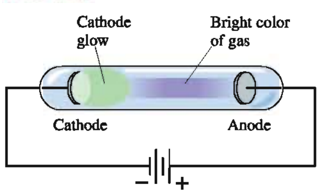
Faraday's discoveries implied that

1. Atoms exist.
2. Electric charges are somehow associated with atoms.
3. There are two different kinds of charge, positive and negative.
4. Electricity is "granular" rather than a continuous fluid. That is, it comes in discrete amounts with a basic unit of charge.

Electrical Conduction in Gases

Faraday also investigated whether electric currents could pass through air. He sealed metal electrodes into a glass tube, lowered the pressure with a primitive vacuum pump, then attached an electrostatic generator. When he started the generator, the gas inside the tube began to glow with a bright purple color! Faraday's device, called a **gas discharge tube,** is shown in FIGURE 38.3.

FIGURE 38.3 Faraday's gas discharge tube.



Faraday's investigations showed that

1. Current flows through a low-pressure gas, creating an electric discharge.
2. The color of the discharge depends on the type of gas in the tube.
3. Regardless of the type of gas, there is a separate, constant glow around the negative electrode (i.e., the cathode). This is called the **cathode glow.**

Today we know the purple color is characteristic of nitrogen, the primary component of air. You are more likely familiar with the reddish-orange color of the neon discharge tubes used for signs, but neon was not discovered until long after Faraday's time. His investigations, though, showed an unexpected connection between the color of the light and the type of atoms in the tube.

Electromagnetic Fields

Perhaps Faraday's most important contributions to physics were in the realms of magnetism and light. You will recall that it was Faraday who introduced the concept of electric and magnetic *fields*. Although these fields were first devised simply as a way of envisioning electric and magnetic processes, Faraday's later studies of electromagnetic induction showed that they have a real existence and real properties. These investigations paved the way for the discovery, about 30 years later, that light is an electromagnetic wave.

Faraday's discoveries were a major step toward providing real *evidence* for the existence of atoms. Altogether, Faraday established that atoms are associated with electricity, he demonstrated that different colors of light are associated with different kinds of atoms, and he prepared the way for showing that light is associated with electricity and magnetism.

Matter, electricity, and light—previously three separate ideas—had been intertwined. Even so, Faraday recognized that he had barely scratched the surface, that far more research was needed before atoms were understood.

Although we know nothing of what an atom is, yet we cannot resist forming some idea of a small particle which represents it to the mind; and though we are in equal, if not greater, ignorance of electricity, so as to be unable to say whether it is a particular matter or matters, or mere motion of ordinary matter, or some third kind of power or agent, yet there is an immensity of facts which justify us in believing that the atoms of matter are in some way endowed or associated with electric powers to which they owe their most striking qualities, and amongst them their mutual chemical affinity. . .

Michael Faraday

38.3 Cathode Rays

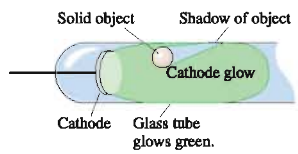
Faraday's invention of the gas discharge tube had two major repercussions. One set of investigations, to which we will return in Section 38.8, led to the development of spectroscopy and eventually to quantum physics. Another set of investigations led to the discovery of the electron.

An important technological breakthrough came in the 1850s with the development of much-improved vacuum pumps. The German scientist Julius Plücker began a study of Faraday's gas discharge tube using lower gas pressures, and he made two important observations:

1. As he reduced the pressure, the colored glow of the gas diminished and the cathode glow became more extended.
2. If the cathode glow extended to the wall of the glass tube, the glass itself emitted a greenish glow at that point.

A few years later, one of Plücker's students found that a solid object sealed inside the tube casts a *shadow* on the glass wall, as shown in FIGURE 38.4. This discovery suggested that the cathode emits *rays* of some form that travel in straight lines but are easily blocked by solid objects. These rays, which are invisible but cause the glass to glow where they strike it, were quickly dubbed **cathode rays.** This name lives on today in the *cathode-ray tube* that forms the picture tube in many televisions and computer display terminals. But naming the rays did nothing to explain them. What were they?

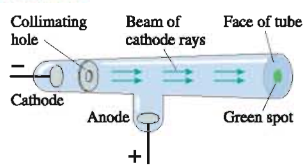
FIGURE 38.4 A solid object in the cathode glow casts a shadow.



Crookes Tubes

The most systematic studies on the new cathode rays were carried out during the 1870s by the English scientist Sir William Crookes. Crookes devised a set of glass tubes, such as the one shown in FIGURE 38.5, that could be used to make careful studies of cathode rays. His primary innovations were to elongate the tube, use yet lower pressure, and introduce a collimating hole for the rays to pass through. The net result was to generate a well-defined beam of cathode rays that created a small glowing spot where they struck the end of the tube. Today we call his design a **Crookes tube.**

FIGURE 38.5 A Crookes tube.



The work of Crookes and others demonstrated that

1. There is an electric current in a tube in which cathode rays are emitted.
2. The rays are deflected by a magnetic field *as if* they are negative charges.
3. Cathodes made of any metal produce cathode rays. Furthermore, the ray properties are independent of the cathode material.
4. The rays can exert forces on objects and can transfer energy to objects. For example, a thin metal foil in the cathode-ray beam glows red hot.

Crookes's experiments led to more questions than they answered. Were the cathode rays some sort of particles? Or a wave? Were the rays themselves the carriers of the electric current, or were they something else that happened to be emitted whenever there was a current? Item 3 is worthy of note because it suggests that the cathode rays are a *fundamental* entity, not a part of the element from which they are emitted.

Although you can read the final answers in a book today, it is important to realize how difficult these questions were at the time and how experimental evidence was used to answer them. Crookes suggested that molecules in the gas collided with the cathode, somehow acquired a negative charge (i.e., became negative ions), and then "rebounded" with great speed as they were repelled by the negative cathode. These "charged molecules" would travel in a straight line, carry energy and momentum, be deflected by a magnetic field, and cause the tube to glow, or *fluoresce,* where they struck the glass. Crookes's theory predicted, of course, that the negative ions should also be deflected by an electric field. Crookes attempted to demonstrate this deflection by sealing electrodes into the tube and creating an electric field, but his efforts were inconclusive. Other than this troublesome difficulty, Crookes's model seemed to explain the observations.

However, Crookes's theory was immediately attacked. Critics noted that the cathode rays could travel the length of a 90-cm-long tube with no discernible deviation from a straight line. But the mean free path for molecules, due to collisions with other molecules, is only about 6 mm at the pressure in Crookes's tubes. There was no chance at all that molecules could travel in a straight line for 150 times their mean free path! It was later discovered that the cathode rays could even penetrate very thin ($\approx 2\ \mu\text{m}$ thick) metal foils, something that no atomic-size particle could do. Crookes's theory, seemingly adequate when it was proposed, was wildly inconsistent with subsequent observations.

But if cathode rays were not particles, what were they? An alternative theory was that the cathode rays were electromagnetic waves. After all, light travels in straight lines, casts shadows, carries energy and momentum, and can, under the right circumstances, cause materials to fluoresce. It was known that hot metals emit light—incandescence—so it seemed plausible that the cathode could be emitting waves. A long path through the gas would present no problem, and it was known by 1890 that radio waves could penetrate thin foils. The major obstacle for the wave theory was the deflection of cathode rays by a magnetic field. But the theory of electromagnetic waves was quite new at the time, and many characteristics of these waves were still unknown. Visible light was not deflected by a magnetic field, but it was easy to think that some other form of electromagnetic waves might be so influenced.

The controversy over particles versus waves was intense. British scientists generally favored particles, but their continental counterparts preferred waves. Such controversies are an integral part of science, for they stimulate the best minds to come forward with new ideas and new experiments.

38.4 J. J. Thomson and the Discovery of the Electron

Shortly after Wilhelm Röntgen's 1895 discovery of x rays, the young English physicist J. J. Thomson began using them to study electrical conduction in gases. He found that x rays could discharge an electroscope and concluded that they must be ionizing the air molecules, thereby making the air conductive.

This simple observation was of profound significance. Until then, the only form of ionization known was the creation of positive and negative ions in solutions where, for example, a molecule such as NaCl splits into two smaller charged pieces. Although the underlying process was not yet understood, the fact that two atoms could acquire charge as a molecule splits apart did not jeopardize the idea that the atoms themselves were indivisible. But after observing that even monatomic gases, such as helium,

could be ionized by x rays, Thomson realized that **the atom itself must have charged constituents that could be separated!** This was the first direct evidence that the atom is a complex structure, not a fundamental, indivisible unit of matter.

Thomson was also performing experiments to investigate the nature of cathode rays. One of his first goals was to establish, once and for all, that cathode rays are charged particles. Other scientists, using a Crookes tube like the one shown in FIGURE 38.6a, had measured an electric current in a cathode-ray beam. Although its presence seemed to demonstrate that the rays are charged particles, proponents of the wave model argued that the current might be a separate, independent event that just happened to be following the same straight line as the cathode rays.

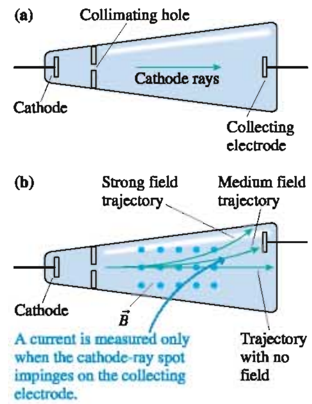
Thomson realized that he could use magnetic deflection of the cathode rays to settle the issue. He built a modified tube, shown in FIGURE 38.6b, in which the collecting electrode was off to the side. With no magnetic field, the cathode rays struck the center of the tube face and created a greenish spot on the glass. No current was measured by the electrode under these circumstances. Thomson then placed the tube in a magnetic field to deflect the cathode rays to the side. He could determine their trajectory by the location of the green spot as it moved across the face of the tube. Just at the point when the field was strong enough to deflect the cathode rays onto the electrode, a current was detected! At an even stronger field, when the cathode rays were deflected completely to the other side of the electrode, the current ceased.

This was the first conclusive demonstration that cathode rays really are negatively charged particles. But why were they not deflected by an electric field? Thomson's first efforts to deflect the cathode rays met with the same inconclusive results that others had found, but his experience with the x-ray ionization of gases soon led him to recognize the difficulty. He realized that the rapidly moving cathode-ray particles must be colliding with the few remaining gas molecules in the tube with sufficient energy to *ionize* them by splitting them into charged pieces. The electric field created by these charges neutralized the field of the electrodes, hence there was no deflection.

Fortunately, vacuum technology was getting ever better. By using the most sophisticated techniques of his day, Thomson was able to lower the pressure to a point where ionization of the gas was not a problem. Then, just as he had expected, the cathode rays *were* deflected by an electric field!

Thomson's experiment was a decisive victory for the charged-particle model, but it still did not indicate anything about the nature of the particles. What were they?

FIGURE 38.6 Experiments to measure the electric current in a cathode-ray tube.



Thomson's Crossed-Field Experiment

Thomson could measure the deflection of cathode-ray particles for various strengths of the magnetic field, but magnetic deflection depends both on the particle's charge-to-mass ratio q/m *and* on its speed. Measuring the charge-to-mass ratio, and thus learning something about the particles themselves, requires some means of determining their speed. To do so, Thomson devised the experiment for which he is most remembered.

Thomson built a tube containing the parallel-plate electrodes visible in the photo in FIGURE 38.7a on the next page. He then placed the tube between the poles of a magnet. FIGURE 38.7b shows that the electric and magnetic fields were perpendicular to each other, thus creating what came to be known as a **crossed-field experiment**.

The magnetic field, which is perpendicular to the particle's velocity $\vec{v}$, exerts a magnetic force on the charged particle of magnitude

$$F_B = qvB \tag{38.1}$$

The magnetic field alone would cause a negatively charged particle to move along an *upward* circular arc. The particle doesn't move in a complete circle because the velocity is large and because the magnetic field is limited in extent. As you learned in Chapter 33, the radius of the arc is

$$r = \frac{mv}{qB} \tag{38.2}$$

J. J. Thomson.

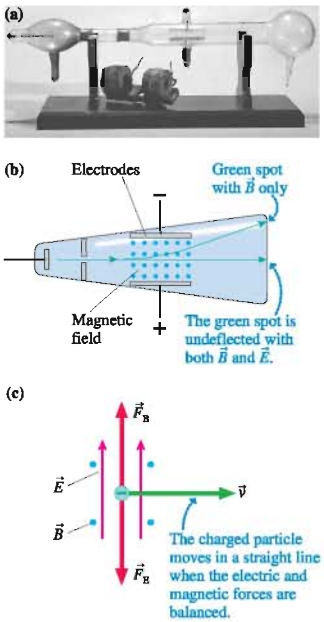


FIGURE 38.7 Thomson's crossed-field experiment to measure the velocity of cathode rays. The photograph shows his original tube and the coils he used to produce the magnetic field.

The net result is to *deflect* the beam of particles upward. It is a straightforward geometry problem to determine the radius of curvature r from the measured deflection.

Thomson's new idea was to create an electric field between the parallel-plate electrodes that would exert a *downward* force on the negative charges, pushing them back toward the center of the tube. The magnitude of the electric force on each particle is

$$F_E = qE \tag{38.3}$$

Thomson adjusted the electric field strength until the cathode-ray beam, in the presence of both electric and magnetic fields, had no deflection and was seen exactly in the center of the tube.

Zero deflection occurs when the magnetic and electric forces exactly balance each other, as **FIGURE 38.7c** shows. The force vectors point in opposite directions, and their magnitudes are equal when

$$F_B = qvB = F_E = qE$$

Notice that the charge q cancels. Once E and B are set, a charged particle can pass undeflected through the crossed fields only if its speed is

$$v = \frac{E}{B} \tag{38.4}$$

By balancing the magnetic force against the electric force, Thomson could determine the speed of the charged-particle beam. Once he knew v, he could use Equation 38.2 to find the charge-to-mass ratio:

$$\frac{q}{m} = \frac{v}{rB} \tag{38.5}$$

Thomson found that the charge-to-mass ratio of cathode rays is $q/m \approx 1 \times 10^{11}$ C/kg. This seems not terribly accurate in comparison to the modern value of 1.76×10^{11} C/kg, but keep in mind both the experimental limitations of his day and the fact that, prior to his work, no one had *any* idea of the charge-to-mass ratio.

EXAMPLE 38.1 A crossed-field experiment

An electron is fired between two parallel-plate electrodes that are 5.0 mm apart and 3.0 cm long. A potential difference ΔV between the electrodes establishes an electric field between them. A 3.0-cm-wide, 1.0 mT magnetic field overlaps the electrodes and is perpendicular to the electric field. When $\Delta V = 0$ V, the electron is deflected by 2.0 mm as it passes between the plates. What value of ΔV will allow the electron to pass through the plates without deflection?

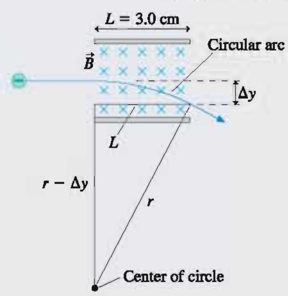
MODEL Assume that the fields between the electrodes are uniform and that they are zero outside the electrodes.

VISUALIZE **FIGURE 38.8** shows an electron passing through the magnetic field between the plates when $\Delta V = 0$ V. The curvature has been exaggerated to make the geometry clear.

SOLVE We can find the needed electric field, and thus ΔV, if we know the electron's speed. We can find the electron's speed from the radius of curvature of its circular arc in a magnetic field. Figure 38.8 shows a right triangle with hypotenuse r and width L. We can use the Pythagorean theorem to write

$$(r - \Delta y)^2 + L^2 = r^2$$

FIGURE 38.8 The electron's trajectory in Example 38.1.



where Δy is the electron's deflection in the magnetic field. This is easily solved to find the radius of the arc:

$$r = \frac{(\Delta y)^2 + L^2}{2\Delta y} = \frac{(0.0020\text{ m})^2 + (0.030\text{ m})^2}{2(0.0020\text{ m})} = 0.226\text{ m}$$

The speed of an electron traveling along an arc with this radius is found from Equation 38.2:

$$v = \frac{erB}{m} = 4.0 \times 10^7 \text{ m/s}$$

Thus the electric field allowing the electron to pass through without deflection is

$$E = vB = 40{,}000 \text{ V/m}$$

The electric field of a parallel-plate capacitor of spacing d is related to the potential difference by $E = \Delta V/d$, so the necessary potential difference is

$$\Delta V = Ed = (40{,}000 \text{ V/m})(0.0050 \text{ m}) = 200 \text{ V}$$

ASSESS A fairly small potential difference is sufficient to counteract the magnetic deflection.

The Electron

Notable as this accomplishment was, Thomson did not stop there. Next he measured q/m for different cathode materials. They were all the same. All metals emit the *same* cathode rays. Thomson then compared his result to the charge-to-mass ratio of the hydrogen ion, known from electrolysis to have a value of $\approx 1 \times 10^8$ C/kg. This value was roughly 1000 times smaller than for the cathode-ray particles, which could imply that a cathode-ray particle has a much larger charge than a hydrogen ion, or a much smaller mass, or some combination of these.

Electrolysis experiments suggested the existence of a basic unit of charge, so it was tempting to assume that the cathode-ray charge was the same as the charge of a hydrogen ion. However, cathode rays were so different from the hydrogen ion that such an assumption could not be justified without some other evidence. To provide that evidence, Thomson called attention to previous experiments showing that cathode rays can penetrate thin metal foils but atoms cannot. This can be true, Thomson argued, only if cathode-ray particles are vastly smaller and thus much less massive than atoms.

In a paper published in 1897, Thomson assembled all of the evidence to announce the discovery that cathode rays are negatively charged particles, that they are much less massive ($\approx 0.1\%$) than atoms, and that they are identical when generated by different elements. In other words, Thomson had discovered a **subatomic particle,** one of the constituents of which atoms themselves are constructed. In recognition of the role this particle plays in electricity, it was later named the **electron.**

Experiments by Thomson and others over the next few years showed that negative particles emitted from hot metal wires (a process discovered by Thomas Edison in his development of the lightbulb) had the same q/m; that one type of radioactive decay (today called *beta radiation*) consisted of particles with the same q/m; and that certain changes in the spectra of atoms when placed in a magnetic field could be understood if the atoms had a charged constituent with the same q/m. By 1900 it was clear to all that electrons were a fundamental building block of atoms. Thomson was awarded the Nobel prize in 1906.

STOP TO THINK 38.1 Thomson's conclusion that cathode-ray particles are *fundamental* constituents of atoms was based primarily on which observation?

a. They have a negative charge.
b. They are the same from all cathode materials.
c. Their mass is much less than that of hydrogen.
d. They penetrate very thin metal foils.

38.5 Millikan and the Fundamental Unit of Charge

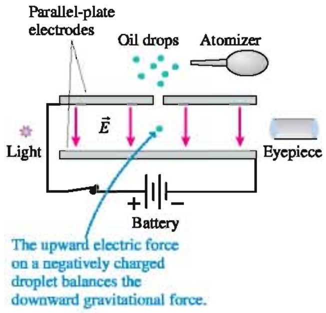


FIGURE 38.9 Millikan's oil-drop apparatus to measure the fundamental unit of charge.

Thomson measured the electron's charge-to-mass ratio and *surmised* that the mass must be much smaller than that of an atom, but clearly it was desirable to measure the charge q directly. This was done in 1906 by the American scientist Robert Millikan.

The **Millikan oil-drop experiment**, as we call it today, is illustrated in FIGURE 38.9. A squeeze-bulb atomizer sprayed out a very fine mist of oil droplets. Millikan found that some these droplets were charged from friction in the sprayer. The charged droplets slowly settled toward a horizontal pair of parallel-plate electrodes, where a few droplets passed through a small hole in the top plate. Millikan observed the drops by shining a bright light between the plates and using an eyepiece to see the droplets' reflections. He then established an electric field by applying a voltage to the plates.

A drop will remain suspended between the plates, moving neither up nor down, if the electric field exerts an upward force on a charged drop that exactly balances the downward gravitational force. The forces balance when

$$m_{\text{drop}}g = q_{\text{drop}}E \tag{38.6}$$

and thus the charge on the drop is measured to be

$$q_{\text{drop}} = \frac{m_{\text{drop}}g}{E} \tag{38.7}$$

Notice that m and q are the mass and charge of the oil droplet, not that of an electron. But because the droplet is charged by acquiring (or losing) electrons, the charge of the droplet should be related to the electron's charge.

The field strength E could be determined accurately from the voltage applied to the plates, so the limiting factor in measuring q_{drop} was Millikan's ability to determine the mass of these small drops. Ideally, the mass could be found by measuring a drop's diameter and using the known density of the oil. However, the drops were too small ($\approx 1\ \mu\text{m}$) to measure accurately by viewing through the eyepiece.

Instead, Millikan devised an ingenious method to find the size of the droplets. Objects this small are *not* in free fall. The air resistance forces are so large that the drops fall with a very small but constant speed. The motion of a sphere through a viscous medium is a problem that had been solved in the 19th century, and it was known that the sphere's terminal speed depends on its radius and on the viscosity of air. So rather than holding the droplets motionless, Millikan used the electric field to cause them to move slowly up and down through a known distance. He could determine the droplets' velocities by timing them with a stopwatch. Then, using the known viscosity of air, he could calculate their radii, compute their masses, and, finally, arrive at a value for their charge. Although it was a somewhat roundabout procedure, Millikan was able to measure the charge on a droplet with an accuracy of $\pm 0.1\%$ (one part in a thousand).

Millikan measured many hundreds of droplets, some for hours at a time, under a wide variety of conditions. He found that some of his droplets were positively charged and some negatively charged, but **all had charges that were integer multiples of a certain minimum charge value.** Millikan concluded that "the electric charges found on ions all have either exactly the same value or else some small exact multiple of that value." That value, the *fundamental unit of charge* that we now call e, is measured to be

$$e = 1.60 \times 10^{-19}\ \text{C}$$

We can then combine the measured e with the measured charge-to-mass ratio e/m to find that the mass of the electron is

$$m_{\text{elec}} = 9.11 \times 10^{-31}\ \text{kg}$$

Taken together, the experiments of Thomson, Millikan, and others provided overwhelming evidence that electric charge comes in discrete units and that *all* charges found in nature are multiples of a fundamental unit of charge we call e.

EXAMPLE 38.2 Suspending an oil drop

Oil has a density of 860 kg/m^3. A 1.0-μm-diameter oil droplet acquires 10 extra electrons as it is sprayed. What potential difference between two parallel plates 1.0 cm apart will cause the droplet to be suspended in air?

MODEL Assume a uniform electric field $E = \Delta V/d$ between the plates.

SOLVE The magnitude of the charge on the drop is $q_{drop} = 10e$. The mass of the charge is related to its density ρ and volume V by

$$m_{drop} = \rho V = \frac{4}{3}\pi R^3 \rho = 4.50 \times 10^{-16}\ \text{kg}$$

where the droplet's radius is $R = 5.0 \times 10^{-7}$ m. The electric field that will suspend this droplet against the force of gravity is

$$E = \frac{m_{drop}g}{q_{drop}} = 2760\ \text{V/m}$$

Establishing this electric field between two plates spaced by $d = 0.010$ m requires a potential difference

$$\Delta V = Ed = 27.6\ \text{V}$$

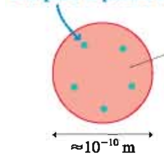
ASSESS Experimentally, this is a very convenient voltage.

38.6 Rutherford and the Discovery of the Nucleus

By 1900, it was clear that atoms are not indivisible but, instead, are constructed of charged particles. Atomic sizes were known to be $\approx 10^{-10}$ m, but the electrons common to all atoms are much smaller and much less massive than the smallest atom. How do they "fit" into the larger atom? What is the positive charge of the atom? Where are the charges located inside the atoms?

Thomson proposed the first model of an atom. Because the electrons are very small and light compared to the whole atom, it seemed reasonable to think that the positively charged part would take up most of the space. Thomson suggested that the atom consists of a spherical "cloud" of positive charge, roughly 10^{-10} m in diameter, in which the smaller negative electrons are embedded. The positive charge exactly balances the negative, so the atom as a whole has no net charge. This model of the atom has often been called the "plum-pudding model" or the "raisin-cake model" for reasons that should be clear from **FIGURE 38.10**.

FIGURE 38.10 Thomson's raisin-cake model of the atom.



Thomson was never able to make any predictions that would enable his model to be tested, and the Thomson atom did not stand the test of time. His model is of interest today primarily to remind us that our current models of the atom are by no means obvious. Science has many sidesteps and dead ends as it progresses.

One of Thomson's students was a New Zealander named Ernest Rutherford. While Rutherford and Thomson were studying the ionizing effects of x rays, in 1896, the French physicist Antoine Henri Becquerel announced the discovery that some new form of "rays" were emitted by crystals of uranium. These rays, like x rays, could expose film, pass through objects, and ionize the air. Yet they were emitted continuously from the uranium without having to "do" anything to it. This was the discovery of **radioactivity**, a topic we'll study in Chapter 43.

With x rays only a year old and cathode rays not yet completely understood, it was not known whether all these various kinds of rays were truly different or merely variations of a single type. Rutherford immediately began a study of these new rays. He quickly discovered that at least two *different* rays are emitted by a uranium crystal. The first, which he called **alpha rays**, were easily absorbed by a piece of paper. The second, **beta rays**, could penetrate through at least 0.1 inch of metal.

As we have already noted, Thomson soon found that beta rays have the same charge-to-mass ratio as cathode rays. The beta rays turned out to be high-speed electrons emitted by the uranium crystal. Rutherford, using similar techniques, showed

that alpha rays are *positively* charged particles. By 1906 he had measured their charge-to-mass ratio to be

$$\frac{q}{m} = \frac{1}{2}\frac{e}{m_H}$$

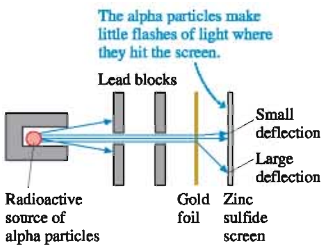
where m_H is the mass of a hydrogen atom. This value could indicate either a singly ionized hydrogen molecule H_2^+ ($q = e, m = 2m_H$) *or* a doubly ionized helium atom He^{++} ($q = 2e, m = 4m_H$).

In an ingenious experiment, Rutherford sealed a sample of radium—an emitter of alpha radiation—into a glass tube. Alpha rays could not penetrate the glass, so the particles were contained within the tube. Several days later, Rutherford used electrodes in the tube to create a discharge and observed the spectrum of the emitted light. He found the characteristic wavelengths of helium, but not those of hydrogen. Alpha rays (or alpha particles, as we now call them) consist of doubly ionized helium atoms (bare helium nuclei) emitted at high speed ($\approx 3 \times 10^7$ m/s) from the sample.

It had been quite a shock to discover that atoms are not indivisible, that they have an inner structure. Now, with the discovery of radioactivity, it appeared that some atoms were not even stable but could spit out various kinds of charged particles! Physics had come a long way from the simple atomic idea of Democritus.

The First Nuclear Physics Experiment

FIGURE 38.11 Rutherford's experiment to shoot high-speed alpha particles through a thin gold foil.

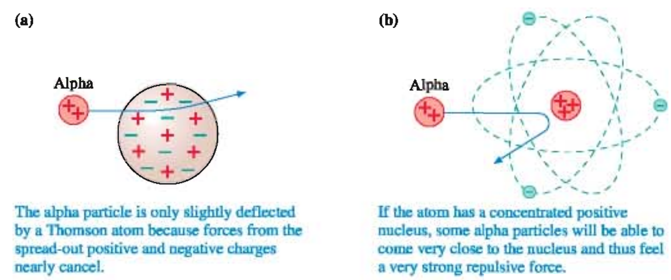


Rutherford soon realized that he could use these high-speed particles to probe inside other atoms. In 1909, Rutherford and his students Hans Geiger and Ernest Marsden set up the experiment shown in FIGURE 38.11 to shoot alpha particles at very thin metal foils. Some of the alpha particles penetrated the foil, but the beam of alpha particles that did so became somewhat spread out. This was not surprising. The alpha particle is charged, and it experiences forces from the positive and negative charges of the atoms as it passes through the foil. According to Thomson's raisin-cake model of the atom, the forces exerted on the alpha particle by the positive atomic charges were expected to roughly cancel the forces from the negative electrons, causing the alpha particles to be deflected only slightly. Indeed, this was the experimenters' initial observation.

At Rutherford's suggestion, Geiger and Marsden set up the apparatus to see if any alpha particles were deflected at *large* angles. It took only a few days to find the answer. Not only were alpha particles deflected at large angles, but a very few were reflected almost straight backward toward the source!

How can we understand this result? FIGURE 38.12a shows that only a small deflection is expected for an alpha particle passing through a Thomson atom. But if an atom has a small, positive core, such as the one in FIGURE 38.12b, a few of the alpha particles can come very close to the core. Because the electric force varies with the inverse square of the distance, the very large force of this very close approach can cause a large-angle scattering or a backward deflection of the alpha particle. This is what Geiger and Marsden were observing.

FIGURE 38.12 Alpha particles interact differently with a concentrated positive nucleus than they would with the spread-out charge in Thomson's model.



Thus the discovery of large-angle scattering of alpha particles led Rutherford to envision an atom in which negative electrons orbit an unbelievably small, massive, positive **nucleus,** rather like a miniature solar system. This is the **nuclear model of the atom.** Notice that nearly all of the atom is empty space—the void!

ActivPhysics Online 19.1

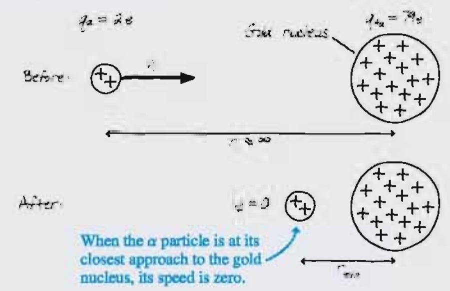
EXAMPLE 38.3 A nuclear physics experiment

An alpha particle is shot with a speed of 2.0×10^7 m/s directly toward the nucleus of a gold atom. What is the distance of closest approach to the nucleus?

MODEL Energy is conserved in electric interactions. Assume that the gold nucleus, which is much more massive than the alpha particle, does not move. Also recall that the exterior electric field and potential of a sphere of charge can be found by treating the total charge as a point charge at the center.

VISUALIZE FIGURE 38.13 is a pictorial representation. The motion is in and out along a straight line.

FIGURE 38.13 A before-and-after pictorial representation of an alpha particle colliding with a nucleus.



SOLVE We are not interested in how long the collision takes or any of the details of the trajectory, so using conservation of energy rather than Newton's laws is appropriate. Initially, when the alpha particle is very far away, the system has only kinetic energy. At the moment of closest approach, just before the alpha particle is reflected, the charges are at rest and the system has only potential energy. The conservation of energy statement $K_f + U_f = K_i + U_i$ is

$$0 + \frac{1}{4\pi\epsilon_0}\frac{q_\alpha q_{Au}}{r_{min}} = \frac{1}{2}mv_i^2 + 0$$

where q_α is the alpha-particle charge and we've treated the gold nucleus as a point charge q_{Au}. The mass m is that of the alpha particle. The solution for r_{min} is

$$r_{min} = \frac{1}{4\pi\epsilon_0}\frac{2q_\alpha q_{Au}}{mv_i^2}$$

The alpha particle is a helium nucleus, so $m = 4\text{ u} = 6.64 \times 10^{-27}$ kg and $q_\alpha = 2e = 3.20 \times 10^{-19}$ C. Gold has atomic number 79, so $q_{Au} = 79e = 1.26 \times 10^{-17}$ C. We can then calculate

$$r_{min} = 2.7 \times 10^{-14}\text{ m}$$

This is only about 1/10,000 the size of the atom itself!

ASSESS We ignored the atom's electrons in this example. In fact, they make almost no contribution to the alpha particle's trajectory. The alpha particle is exceedingly massive compared to the electrons, and the electrons are spread out over a distance very large compared to the size of the nucleus. Hence the alpha particle easily pushes them aside without any noticeable change in its velocity.

Rutherford went on to make careful experiments of how the alpha particles scattered at different angles. From these experiments he deduced that the diameter of the atomic nucleus is $\approx 1 \times 10^{-14}\text{ m} = 10\text{ fm}$ (1 fm = 1 femtometer = 10^{-15} m), increasing a little for elements of higher atomic number and atomic mass.

It may seem surprising to you that the Rutherford model of the atom, with its solar system analogy, was not Thomson's original choice. However, scientists at the time could not imagine matter having the extraordinarily high density implied by a small nucleus. Neither could they understand what holds the nucleus together, why the positive charges do not push each other apart. Thomson's model, in which the positive charge was spread out and balanced by the negative electrons, actually made more sense. It would be several decades before the forces holding the nucleus together began to be understood, but Rutherford's evidence for a very small nucleus was indisputable.

I remember two or three days later Geiger coming to me in great excitement and saying, "We have been able to get some of the alpha particles coming backward." It was quite the most incredible event that has ever happened to me in my life. It was almost as if you fired a 15-inch shell at a piece of tissue paper and it came back and hit you. . . . It was then that I had the idea of an atom with a minute massive center, carrying a charge.

Ernest Rutherford

a. Up b. Down c. Into the page d. Out of the page

The Electron Volt

The joule is a unit of appropriate size in mechanics and thermodynamics, where we dealt with macroscopic objects, but it is poorly matched to the needs of atomic physics. It will be very useful to have an energy unit appropriate to atomic and nuclear events.

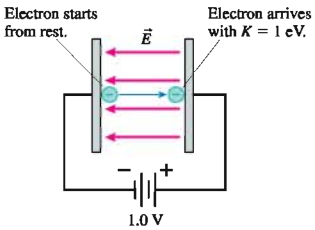

FIGURE 38.14 An electron accelerating across a 1 V potential difference gains 1 eV of kinetic energy.

FIGURE 38.14 shows an electron accelerating (in a vacuum) from rest across a parallel-plate capacitor with a 1.0 V potential difference. What is the electron's kinetic energy when it reaches the positive plate? We know from energy conservation that $K_f + qV_f = K_i + qV_i$, where $U = qV$ is the electric potential energy. $K_i = 0$ because the electron starts from rest, and the electron's charge is $q = -e$. Thus

$$K_f = -q(V_f - V_i) = -q\Delta V = e\Delta V = (1.60 \times 10^{-19}\,\text{C})(1.0\,\text{V})$$
$$= 1.60 \times 10^{-19}\,\text{J}$$

Let us define a new unit of energy, called the **electron volt**, as

$$1 \text{ electron volt} = 1 \text{ eV} \equiv 1.60 \times 10^{-19}\,\text{J}$$

With this definition, the kinetic energy gained by the electron in our example is

$$K_f = 1 \text{ eV}$$

In other words, **1 electron volt is the kinetic energy gained by an electron (or proton) if it accelerates through a potential difference of 1 volt.**

NOTE ▶ The abbreviation eV uses a lowercase e but an uppercase V. Units of keV (10^3 eV), MeV (10^6 eV), and GeV (10^9 eV) are common. ◀

The electron volt can be a troublesome unit. One difficulty is its unusual name, which looks less like a unit than, say, "meter" or "second." A more significant difficulty is that the name suggests a relationship to volts. But *volts* are units of electric potential, whereas this new unit—with an admittedly confusing name—is a unit of energy! It is crucial to distinguish between the *potential* V, measured in volts, and an *energy* that can be measured either in joules or in electron volts. You can now use electron volts anywhere that you would previously have used joules. Doing so is no different from converting back and forth between pressure units of pascals and atmospheres.

NOTE ▶ To reiterate, the electron volt is a unit of *energy,* convertible to joules, and not a unit of potential. Potential is always measured in volts. However, the joule remains the SI unit of energy. It will be useful to express energies in eV, but you *must* convert this energy to joules before doing most calculations. ◀

EXAMPLE 38.4 The speed of an alpha particle

Alpha particles are usually characterized by their kinetic energy in MeV. What is the speed of an 8.3 MeV alpha particle?

SOLVE Alpha particles are helium nuclei, having $m = 4\text{ u} = 6.64 \times 10^{-27}$ kg. The kinetic energy of this alpha particle is 8.3×10^6 eV. First, we convert the energy to joules:

$$K = 8.3 \times 10^6\,\text{eV} \times \frac{1.60 \times 10^{-19}\,\text{J}}{1.00\,\text{eV}} = 1.33 \times 10^{-12}\,\text{J}$$

Now we can find the speed:

$$K = \frac{1}{2}mv^2 = 1.33 \times 10^{-12}\,\text{J}$$

$$v = \sqrt{\frac{2K}{m}} = 2.0 \times 10^7\,\text{m/s}$$

This was the speed of the alpha particle in Example 38.3.

EXAMPLE 38.5 Energy of an electron

In a simple model of the hydrogen atom, the electron orbits the proton at 2.19×10^6 m/s in a circle with radius 5.29×10^{-11} m. What is the atom's energy in eV?

MODEL The electron has a kinetic energy of motion, and the electron + proton system has an electric potential energy.

SOLVE The potential energy is that of two point charges, with $q_{proton} = +e$ and $q_{elec} = -e$. Thus

$$E = K + U = \frac{1}{2}m_{elec}v^2 + \frac{1}{4\pi\epsilon_0}\frac{(e)(-e)}{r} = -2.17 \times 10^{-18}\text{ J}$$

Conversion to eV gives

$$E = -2.17 \times 10^{-18}\text{ J} \times \frac{1\text{ eV}}{1.60 \times 10^{-19}\text{ J}} = -13.6\text{ eV}$$

ASSESS The negative energy reflects the fact that the electron is *bound* to the proton. You would need to *add* energy to remove the electron.

Using the Nuclear Model

The nuclear model of the atom makes it easy to understand and picture such processes as ionization. Because electrons orbit a positive nucleus, an x-ray photon or a rapidly moving particle, such as another electron, can knock one of the orbiting electrons away, creating a positive ion. Removing one electron makes a singly charged ion, with $q = +e$. Removing two electrons creates a doubly charged ion, with $q = +2e$. This is shown for lithium (atomic number 3) in FIGURE 38.15.

FIGURE 38.15 Different ionization stages of the lithium atom ($Z = 3$).

The nuclear model also allows us to understand why, during chemical reactions and when an object is charged by rubbing, electrons are easily transferred but protons are not. The protons are tightly bound in the nucleus, shielded by all the electrons, but outer electrons are easily stripped away. Rutherford's nuclear model has explanatory power that was lacking in Thomson's model.

EXAMPLE 38.6 The ionization energy of hydrogen

What is the minimum energy required to ionize a hydrogen atom? The electron orbits the proton at 2.19×10^6 m/s in a circle with radius 5.29×10^{-11} m.

SOLVE In Example 38.5 we found that the atom's energy is $E_i = -13.6$ eV. Ionizing the atom means removing the electron and taking it very far away. As $r \to \infty$, the potential energy becomes zero. Further, using the least possible energy to ionize the atom will leave the electron, when it is very far away, very nearly at rest. Thus the atom's energy after ionization is $E_f = K_f + U_f = 0 + 0 = 0$ eV. This is *larger* than E_i by 13.6eV, so the minimum energy that is required to ionize a hydrogen atom is 13.6 eV. This is called the atom's *ionization energy.* If the electron receives ≥ 13.6 eV (2.17×10^{-18} J) of energy from a photon, or in a collision with another electron, or by any other means, it will be knocked out of the atom and leave a H^+ ion behind.

STOP TO THINK 38.3 Carbon is the sixth element in the periodic table. How many electrons are in a C^{++} ion?

38.7 Into the Nucleus

Chapter 43 will discuss nuclear physics in more detail, but it will be helpful to give a brief overview of the nucleus. The relative masses of many of the elements were known from chemistry experiments by the mid-19th century. By arranging the elements in order of ascending mass, and noting recurring regularities in their chemical properties, the Russian chemist Dmitri Mendeleev first proposed the periodic table of the elements in 1872. But what did it mean to say that hydrogen was atomic number 1, helium number 2, lithium number 3, and so on?

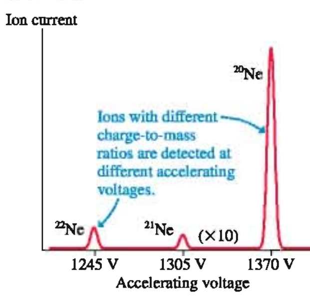
It soon became known that hydrogen atoms can be only singly ionized, producing H^+. A doubly ionized H^{++} is never observed. Helium, by contrast, can be both singly and doubly ionized, creating He^+ and He^{++}, but He^{+++} is not observed. Once Thomson discovered the electron and Millikan established the fundamental unit of charge, it seemed fairly clear that a hydrogen atom contains only one electron and one unit of positive charge, helium has two electrons and two units of positive charge, and so on. Thus the **atomic number** of an element, which is always an integer, describes the number of electrons (of a neutral atom) and the number of units of positive charge in the nucleus. The atomic number is represented by Z, so hydrogen is $Z = 1$, helium $Z = 2$, and lithium $Z = 3$. Elements are listed in the periodic table by their atomic number.

Rutherford's discovery of the nucleus quickly led to the recognition that the positive charge is associated with a positive subatomic particle called the **proton.** The proton's charge is $+e$, equal in magnitude but opposite in sign to the electron's charge. Further, because nearly all the atomic mass is associated with the nucleus, the proton is much more massive than the electron. According to Rutherford's nuclear model, atoms with atomic number Z consist of Z negative electrons, with net charge $-Ze$, orbiting a massive nucleus that contains protons and has net charge $+Ze$. The Rutherford atom went a long way toward explaining the periodic table.

But there was a problem. Helium, with atomic number 2, has twice as many electrons as hydrogen. Lithium, $Z = 3$, has three electrons. But it was known from chemistry measurements that helium is *four times* as massive as hydrogen and lithium is *seven times* as massive. If a nucleus contains Z protons to balance the Z orbiting electrons, and if nearly all the atomic mass is contained in the nucleus, then helium should be simply twice as massive as hydrogen and lithium three times as massive. Something else must be present in the nucleus to make the atoms more massive than our simple nuclear model predicts.

The Neutron

FIGURE 38.16 The mass spectrum of neon.



About 1910, Thomson and his student Francis Aston developed a device called a **mass spectrometer** for measuring the charge-to-mass ratios of atomic ions. (A mass spectrometer was the subject of homework problem 64 in Chapter 33.) As Aston and others began collecting data, they soon found that many elements consist of atoms of *differing* mass! Neon, for example, had been assigned an atomic mass of 20. But Aston found, as the data of FIGURE 38.16 show, that while 91% of neon atoms have mass $m = 20$ u, 9% have $m = 22$ u and a very small percentage have $m = 21$ u. Chlorine was found to be a mixture of 75% chlorine atoms with $m = 35$ u and 25% chlorine atoms with $m = 37$ u, both having atomic number $Z = 17$.

These difficulties were not resolved until the discovery, in 1932, of a third subatomic particle. This particle has essentially the same mass as a proton but *no* electric charge. It is called the **neutron.** Neutrons reside in the nucleus, with the protons, where they contribute to the mass of the atom but not to its charge. As you'll see in Chapter 43, neutrons help provide the "glue" that holds the nucleus together.

The neutron was the missing link needed to explain why atoms of the same element can have different masses. We now know that every atom with atomic number Z has a

nucleus containing Z protons with charge $+Ze$. In addition, as shown in FIGURE 38.17, the nucleus contains N neutrons. There are a *range* of neutron numbers that happily form a nucleus with Z protons, creating a series of nuclei having the same Z-value (i.e., they are all the same chemical element) but different masses. Such a series of nuclei are called **isotopes.**

Chemical behavior is determined by the orbiting electrons. All isotopes of one element have the same number Z of orbiting electrons (if the atoms are electrically neutral) and have the same chemical properties. But different isotopes of the same element can have quite different nuclear properties. In addition, macroscopic behavior that depends on mass, such as the diffusion of a gas, can slightly favor one isotope over another.

An atom's **mass number** A is defined to be $A = Z + N$. It is the total number of protons and neutrons in a nucleus. The mass number, which is dimensionless, is *not* the same thing as the atomic mass m. By definition, A is an integer. But because the proton and neutron masses are both ≈ 1 u, the mass number A is *approximately* the mass in atomic mass units.

The notation used to label isotopes is ^{A}Z, where the mass number A is given as a *leading* superscript. The proton number Z is not specified by an actual number but, equivalently, by the chemical symbol for that element. The most common isotope of neon has $Z = 10$ protons and $N = 10$ neutrons. Thus it has mass number $A = 20$ and it is labeled ^{20}Ne. The neon isotope ^{22}Ne has $Z = 10$ protons (that's what makes it neon) and $N = 12$ neutrons. Helium has the two isotopes shown in FIGURE 38.18. The rare ^{3}He is only 0.0001% abundant, but it can be isolated and has important uses in scientific research.

FIGURE 38.17 The nucleus of an atom contains protons and neutrons.

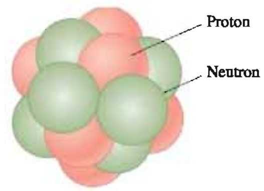


FIGURE 38.18 The two isotopes of helium. ^{3}He is only 0.0001% abundant.

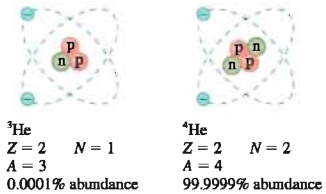


STOP TO THINK 38.4 Carbon is the sixth element in the periodic table. How many protons and how many neutrons are there in a nucleus of the isotope ^{14}C?

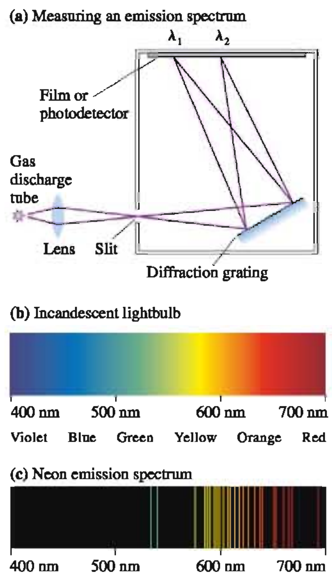
38.8 The Emission and Absorption of Light

While some scientists were investigating the structure of matter, others were busy exploring how matter emits and absorbs light. Their discoveries would also, in the early years of the 20th century, come to bear on the issue of atomic structure.

The distinctive pattern of wavelengths emitted by a source of light is called its *spectrum.* FIGURE 38.19a shows how a spectrum is measured. By the end of the 19th century, scientists had discovered two distinct types of spectra:

- Hot, self-luminous objects, such as the sun or an incandescent lightbulb, form a rainbow-like **continuous spectrum** in which light is emitted at every possible wavelength. FIGURE 38.19b is a continuous spectrum.
- In contrast, the light emitted by one of Faraday's gas discharge tubes contains only certain discrete, individual wavelengths. Such a spectrum is called a **discrete spectrum.** Each wavelength in a discrete spectrum is called a **spectral line** because of its appearance in photographs such as FIGURE 38.19c.

FIGURE 38.19 A grating spectrometer is used to study the emission of light.

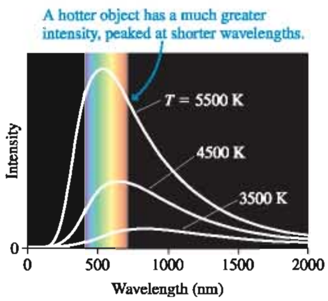


Continuous Spectra and Blackbody Radiation

Cool lava is black, but lava heated to a high temperature glows red and, if hot enough, yellow. A tungsten wire, dark gray at room temperature, emits bright white light when heated by a current through it—thus becoming the bright filament in an incandescent lightbulb. This temperature-dependent emission of electromagnetic waves was called *thermal radiation* when we studied it as the mechanism of heat transfer in Chapter 17.

Black lava glows brightly when hot.

FIGURE 38.20 Blackbody radiation spectra.



Recall that the heat energy Q radiated in a time interval Δt by an object with surface area A and absolute temperature T is given by

$$\frac{Q}{\Delta t} = e\sigma A T^4 \tag{38.8}$$

where $\sigma = 5.67 \times 10^{-8}\ \mathrm{W/m^2\,K^4}$ is the Stefan-Boltzmann constant. Notice the very strong fourth-power dependence on temperature.

The parameter e in Equation 38.8 is the *emissivity* of the surface, a measure of how effectively it radiates. The value of e ranges from 0 to 1. A perfectly absorbing—and thus perfectly emitting—object with $e = 1$ is called a *blackbody*, and the thermal radiation emitted by a blackbody is called **blackbody radiation.** Charcoal is an excellent approximation of a blackbody.

Our interest in Chapter 17 was the amount of energy radiated. Now we want to examine the spectrum of that radiation. If we measure the spectrum of a blackbody at three temperatures, 3500 K, 4500 K, and 5500 K, the data appear as in FIGURE 38.20. These continuous curves are called *blackbody spectra*. There are four important features of the spectra:

- All blackbodies at the same temperature emit exactly the same spectrum. **The spectrum depends on only an object's temperature, not the material of which it is made.**
- Increasing the temperature increases the radiated intensity at *all* wavelengths. **Making the object hotter causes it to emit more radiation across the entire spectrum.**
- Increasing the temperature causes the peak intensity to shift toward shorter wavelengths. **The higher the temperature, the shorter the wavelength of the peak of the spectrum.**
- The visible rainbow that we see is only a small portion of the continuous blackbody spectrum. Much of the emission is infrared, and very hot objects also radiate ultraviolet wavelengths.

The wavelength corresponding to the peak of the intensity graph is given by

$$\lambda_{peak}(\text{in nm}) = \frac{2.90 \times 10^6\ \text{nm K}}{T} \tag{38.9}$$

where T must be in kelvin. Equation 38.9 is known as **Wien's law.**

EXAMPLE 38.7 Finding peak wavelengths

What are the peak wavelengths and the corresponding spectral regions for thermal radiation from the sun, a glowing ball of gas with a surface temperature of 5800 K, and from the earth, whose average surface temperature is 15°C?

MODEL The sun and the earth are well approximated as blackbodies.

SOLVE The sun's wavelength of peak intensity is given by Wien's law:

$$\lambda_{peak} = \frac{2.90 \times 10^6\ \text{nm K}}{5800\ \text{K}} = 500\ \text{nm}$$

This is right in the middle of the visible spectrum. The earth's wavelength of peak intensity is

$$\lambda_{peak} = \frac{2.90 \times 10^6\ \text{nm K}}{288\ \text{K}} = 10{,}000\ \text{nm}$$

where we converted the surface temperature to kelvin before computing. This is rather far into the infrared portion of the spectrum, which is not surprising because we don't "see" the earth glowing.

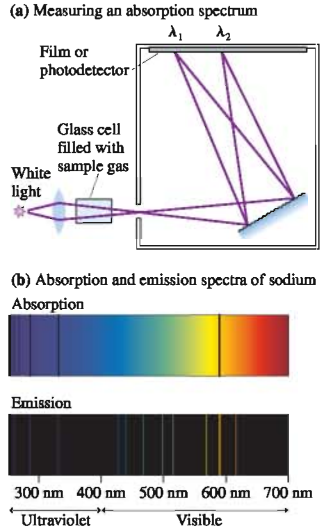
ASSESS The difference between these two wavelengths is quite important for understanding the earth's greenhouse effect. Most of the energy from the sun—it's spectrum is much like the highest curve in Figure 38.20—arrives as visible light. The earth's atmosphere is transparent to visible wavelengths, so this energy reaches the ground and is absorbed. The earth must radiate an equal amount of energy back to space, but it does so with long-wavelength infrared radiation. These wavelengths are strongly absorbed by some gases in the atmosphere, so the atmosphere acts as a blanket to keep the earth's surface warmer than it would be otherwise.

That all blackbodies at the same temperature emit the same spectrum was an unexpected discovery. Why should this be? It seemed that a combination of thermodynamics and Maxwell's new theory of electromagnetic waves ought to provide a convincing explanation, but many of the top scientists of the late 19th century tried and failed to come up with a theoretical justification for the curves seen in Figure 38.20.

Discrete Spectra

The discrete emission spectrum of a hot, low-density gas, such as the neon spectrum in Figure 38.19c, stands in sharp contrast to the continuous blackbody spectrum of a glowing solid. Not only do gases emit discrete wavelengths, but it was soon discovered that they also absorb discrete wavelengths. **FIGURE 38.21a** shows an absorption experiment in which white light passes through a sample of gas. Without the gas, the white light would expose the film with a continuous rainbow spectrum. Any wavelengths absorbed by the gas are missing, and the film is dark at that wavelength. **FIGURE 38.21b** shows, for sodium vapor, that only certain discrete wavelengths are absorbed.

FIGURE 38.21 Measuring an absorption spectrum.

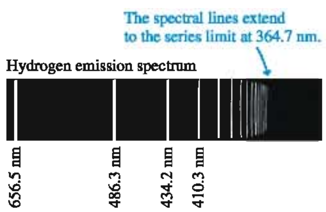


Although the emission and absorption spectra of a gas are both discrete, there is an important difference: **Every wavelength absorbed by the gas is also emitted, but *not* every emitted wavelength is absorbed.** Figure 38.21b shows that the wavelengths in the absorption spectrum are a subset of those in the emission spectrum. All the absorption wavelengths are prominent in the emission spectrum, but there are many emission wavelengths for which no absorption occurs.

What causes atoms to emit or absorb light? Why a discrete spectrum? Why are some wavelengths emitted but not absorbed? Why is each element different? Nineteenth-century physicists struggled with these questions but could not answer them. Ultimately, their inability to understand the emission and absorption of light forced scientists to the unwelcome realization that classical physics was simply incapable of providing an understanding of atoms.

The only encouraging sign came from an unlikely source. While the spectra of other atoms have dozens or even hundreds of wavelengths, the emission spectrum of hydrogen, seen in **FIGURE 38.22**, is very simple and regular. If any spectrum could be understood, it should be that of the first element in the periodic table. The breakthrough came in 1885, not by an established and recognized scientist but by a Swiss schoolteacher, Johann Balmer. Balmer showed that the wavelengths in the hydrogen spectrum could be represented by the simple formula

FIGURE 38.22 The hydrogen emission spectrum.



$$\lambda = \frac{91.18\text{ nm}}{\left(\dfrac{1}{2^2} - \dfrac{1}{n^2}\right)}, \qquad n = 3, 4, 5, \ldots \qquad (38.10)$$

Balmer's story was told more completely in Section 25.1, to which you should refer.

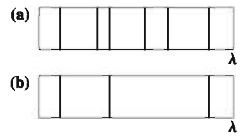
Later experimental evidence, as ultraviolet and infrared spectroscopy developed, showed that Balmer's result could be generalized to

$$\lambda = \frac{91.18\text{ nm}}{\left(\dfrac{1}{m^2} - \dfrac{1}{n^2}\right)}, \qquad m = 1, 2, 3, \ldots \qquad n = m + 1, m + 2, \ldots \qquad (38.11)$$

We now refer to Equation 38.11 as the **Balmer formula**, although Balmer himself suggested only the original version of Equation 38.10 in which $m = 2$. Other than at the highest levels of resolution, where new details appear that need not concern us in this text, the Balmer formula accurately describes *every* wavelength in the emission spectrum of hydrogen.

The Balmer formula is what we call *empirical knowledge*. It is an accurate mathematical representation found empirically—that is, through experimental evidence—but it does not rest on any physical principles or physical laws. Balmer's formula was useful, but no one was able to *derive* Balmer's formula from Newtonian mechanics or the theory of electromagnetism. Yet the formula was so simple that it must, everyone agreed, have a simple explanation. It would take 30 years to find it.

STOP TO THINK 38.5 These spectra are due to the same element. Which one is an emission spectrum and which is an absorption spectrum?

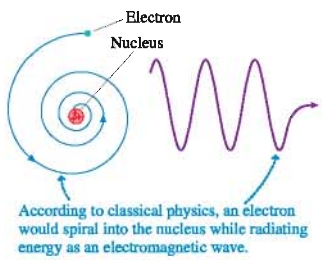


38.9 Classical Physics at the Limit

At the start of the 19th century, only a few scientists thought that matter consists of atoms. By century's end, there was substantial evidence not only for atoms but also for the existence of charged subatomic particles. The explorations into atomic structure culminated with Rutherford's nuclear model.

Rutherford's nuclear model of the atom matched the experimental evidence about the *structure* of atoms, but it had two serious shortcomings. According to Maxwell's theory of electricity and magnetism, the orbiting electrons in a Rutherford atom should act as small antennas and radiate electromagnetic waves. That sounds encouraging, because we know that atoms can emit light, but it was easy to show that a Rutherford atom would radiate a *continuous* rainbow-like spectrum. Thus one failure of Rutherford's model was an inability to predict the discrete nature of emission and absorption spectra.

FIGURE 38.23 The fate of a Rutherford atom.



In addition, the atoms would continuously lose energy as they radiated electromagnetic waves. As **FIGURE 38.23** shows, this would cause the electrons to spiral into the nucleus! Calculations showed that a Rutherford atom can last no more than about a microsecond. In other words, classical Newtonian mechanics and electromagnetism predict that an atom in which electrons orbit a nucleus would be highly unstable and would immediately self-destruct. This clearly does not happen.

The experimental efforts of the late 19th century had been impressive, and there could be no doubt about the existence of electrons, about the small positive nucleus, and about the unique discrete spectrum emitted by each atom. But the theoretical framework for understanding such observations had lagged behind. As the new century dawned, physicists could not explain the structure of atoms, could not explain the stability of matter, could not explain discrete spectra or black body radiation, and could not explain the origin of x rays or radioactivity.

Yet few physicists were willing to abandon the successful and long-cherished theories of classical physics. Most considered these "problems" with atoms to be minor discrepancies that would soon be resolved. But classical physics had, indeed, reached its limit, and a whole new generation of brilliant young physicists, with new ideas, was about to take the stage. Among the first was an unassuming young man in Bern, Switzerland. His scholastic record had been mediocre, and the best job he could find upon graduation was as a clerk in the patent office, examining patent applications. He needed the job, having recently married a fellow student due, at least in part, to a child conceived out of wedlock. His name was Albert Einstein.

SUMMARY

The goal of Chapter 38 has been to understand how scientists discovered the properties of atoms and how these discoveries led to the need for a new theory of light and matter.

Important Concepts/Experiments

Nineteenth-century scientists focused on understanding matter, electricity, and light. Faraday's invention of the gas discharge tube launched two important avenues of inquiry.

Cathode Rays and Atomic Structure

Thomson found that cathode rays are negative, subatomic particles. These were soon named **electrons.** Electrons are

- Constituents of atoms.
- The fundamental units of negative charge.

Rutherford discovered the atomic **nucleus.** His nuclear model of the atom proposes

- A very small, dense positive nucleus.
- Orbiting negative electrons.

Later, different **isotopes** were recognized to contain different numbers of **neutrons** in a nucleus with the same number of **protons.**

Atomic Spectra and the Nature of Light

The spectra emitted by the gas in a discharge tube consist of discrete wavelengths.

- Every element has a unique spectrum.
- Every spectral line in an element's absorption spectrum is present in its emission spectrum, but not all emission lines are seen in the absorption spectrum.

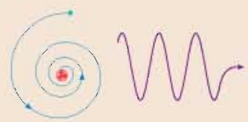
Balmer found that the wavelengths of the hydrogen emission spectrum are

$$\lambda = \frac{91.18\text{ nm}}{\left(\dfrac{1}{m^2} - \dfrac{1}{n^2}\right)}, \qquad m = 1, 2, 3, \ldots \qquad n = m+1, m+2, \ldots$$

The end of classical physics. . .

Atomic spectra had to be related to atomic structure, but no one could understand how. Classical physics could not explain

- The stability of matter.
- Discrete atomic spectra.
- Continuous blackbody spectra.



Applications

Millikan's oil-drop experiment measured the fundamental unit of charge:

$$e = 1.60 \times 10^{-19}\text{ C}$$

One **electron volt** (1 eV) is the energy an electron or proton (charge $\pm e$) gains by accelerating through a potential difference of 1 V:

$$1\text{ eV} = 1.60 \times 10^{-19}\text{ J}$$

Terms and Notation

Problems labeled integrate significant material from earlier chapters.

CONCEPTUAL QUESTIONS

1. a. Summarize the experimental evidence *prior* to the research of Thomson by which you might conclude that cathode rays are some kind of particle.
   b. Summarize the experimental evidence *prior* to the research of Thomson by which you might conclude that cathode rays are some kind of wave.
2. Thomson observed deflection of the cathode-ray particles due to magnetic and electric fields, but there was no observed deflection due to gravity. Why not?
3. What was the significance of Thomson's experiment in which an off-center electrode was used to collect charge deflected by a magnetic field?
4. What is the evidence by which we know that an electron from an iron atom is identical to an electron from a copper atom?
5. a. Describe the experimental evidence by which we know that the nucleus is made up not just of protons.
   b. The neutron is not easy to isolate or control because it has no charge that would allow scientists to manipulate it. What evidence allowed scientists to determine that the mass of the neutron is almost the same as the mass of a proton?
6. Rutherford studied alpha particles using the crossed-field technique Thomson had invented to study cathode rays. Assuming that $v_{alpha} \approx v_{cathode\ ray}$ (which turns out to be true), would the deflection of an alpha particle by a magnetic field be larger, smaller, or the same as the deflection of a cathode-ray particle by the same field? Explain.
7. Once Thomson showed that atoms consist of very light negative electrons and a much more massive positive charge, why didn't physicists immediately consider a solar-system model of electrons orbiting a positive nucleus? Why would physicists in 1900 object to such a model?
8. Explain why the observation of alpha particles scattered at very large angles led Rutherford to reject Thomson's model of the atom and to propose a nuclear model.
9. Identify the element, the isotope, and the charge state of each atom in FIGURE Q38.9. Give your answer in symbolic form, such as $^4He^+$ or $^8Be^-$.

EXERCISES AND PROBLEMS

Exercises

Section 38.3 Cathode Rays

Section 38.4 J. J. Thomson and the Discovery of the Electron

1. | The current in a Crookes tube is 10 nA. How many electrons strike the face of the glass tube each second?
2. || An electron in a cathode-ray beam passes between 2.5-cm-long parallel-plate electrodes that are 5.0 mm apart. A 2.0 mT, 2.5-cm-wide magnetic field is perpendicular to the electric field between the plates. The electron passes through the electrodes without being deflected if the potential difference between the plates is 600 V.
   a. What is the electron's speed?
   b. If the potential difference between the plates is set to zero, what is the electron's radius of curvature in the magnetic field?
3. | Electrons pass through the parallel electrodes shown in FIGURE EX38.3 with a speed of 5.0×10^6 m/s. What magnetic field strength and direction will allow the electrons to pass through without being deflected? Assume that the magnetic field is confined to the region between the electrodes.

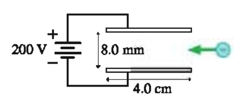

FIGURE EX38.3

Section 38.5 Millikan and the Fundamental Unit of Charge

4. | A 0.80-μm-diameter oil droplet is observed between two parallel electrodes spaced 11 mm apart. The droplet hangs motionless if the upper electrode is 20 V more positive than the lower electrode. The density of the oil is 885 kg/m^3.
   a. What is the droplet's mass?
   b. What is the droplet's charge?
   c. Does the droplet have a surplus or a deficit of electrons? How many?

5. || An oil droplet with 15 excess electrons is observed between two parallel electrodes spaced 12 mm apart. The droplet hangs motionless if the upper electrode is 25 V more positive than the lower electrode. The density of the oil is 860 kg/m^3. What is the radius of the droplet?

6. | Suppose that in a hypothetical oil-drop experiment you measure the following values for the charges on the drops: 3.99×10^{-19} C, 6.65×10^{-19} C, 2.66×10^{-19} C, 10.64×10^{-19} C, and 9.31×10^{-19} C. What is the largest value of the fundamental unit of charge that is consistent with your measurements?

Section 38.6 Rutherford and the Discovery of the Nucleus

Section 38.7 Into the Nucleus

7. | Determine:
   a. The speed of a 100 eV electron.
   b. The speed of a 5 MeV neutron.
   c. The specific type of particle that has 2.09 MeV of kinetic energy when moving with a speed of 1.0×10^7 m/s.

8. | Determine:
   a. The speed of a 6 MeV proton.
   b. The speed of a 20 MeV helium atom.
   c. The specific type of particle that has 1.14 keV of kinetic energy when moving with a speed of 2.0×10^7 m/s.

9. || Express in eV (or keV or MeV if more appropriate):
   a. The kinetic energy of an electron moving with a speed of 5.0×10^6 m/s.
   b. The potential energy of an electron and a proton 0.10 nm apart.
   c. The kinetic energy of a proton that has accelerated from rest through a potential difference of 5000 V.

10. || Express in eV (or keV or MeV if more appropriate):
    a. The kinetic energy of a Li^{++} ion that has accelerated from rest through a potential difference of 5000 V.
    b. The potential energy of two protons 10 fm apart.
    c. The kinetic energy, just before impact, of a 200 g ball dropped from a height of 1.0 m.

11. || A parallel-plate capacitor with a 1.0 mm plate separation is charged to 75 V. With what kinetic energy, in eV, must a proton be launched from the negative plate if it is just barely able to reach the positive plate?

12. || A proton is shot straight outward with 520 eV of kinetic energy from the surface of a 1.0-mm-diameter glass bead that has been charged to 0.20 nC. What is the proton's kinetic energy, in eV, when it is 2.0 mm from the surface?

13. | How many electrons, protons, and neutrons are contained in the following atoms or ions: (a) ^{9}Be, (b) $^{14}N^{+}$, and (c) $^{13}C^{++}$?

14. | How many electrons, protons, and neutrons are contained in the following atoms or ions: (a) ^{10}B, (b) $^{13}N^{+}$, and (c) $^{17}O^{+++}$?

15. | Write the symbol for an atom or ion with:
    a. four electrons, four protons, and six neutrons.
    b. four electrons, six protons, and five neutrons.

16. | Write the symbol for an atom or ion with:
    a. one electron, one proton, and two neutrons.
    b. seven electrons, eight protons, and ten neutrons.

17. | Consider the gold isotope ^{197}Au.
    a. How many electrons, protons, and neutrons are in a neutral ^{197}Au atom?
    b. The gold nucleus has a diameter of 14.0 fm. What is the density of matter in a gold nucleus?
    c. The density of lead is 11,400 kg/m^3. How many times the density of lead is your answer to part b?

18. | Consider the lead isotope ^{207}Pb.
    a. How many electrons, protons, and neutrons are in a neutral ^{207}Pb atom?
    b. The lead nucleus has a diameter of 14.2 fm. What are the electric potential and the electric field strength at the surface of a lead nucleus?

Section 38.8 The Emission and Absorption of Light

19. | Figure 38.22 identified the wavelengths of four lines in the spectrum of hydrogen.
    a. Determine the Balmer formula n and m values for these wavelengths.
    b. Predict the wavelength of the fifth line in the spectrum.

20. | Figure 38.22 identified the wavelengths of four lines in the spectrum of hydrogen.
    a. Determine the Balmer formula n and m values for these wavelengths.
    b. Figure 38.22 labels a feature called the *series limit*, although no spectral line is present at that point. Verify the wavelength of the series limit.

21. | The wavelengths in the hydrogen spectrum with $m = 1$ form a series of spectral lines called the Lyman series. Calculate the wavelengths of the first four members of the Lyman series.

22. | Two of the wavelengths emitted by a hydrogen atom are 102.6 nm and 1876 nm.
    a. What are the m and n values for each of these wavelengths?
    b. For each of these wavelengths, is the light infrared, visible, or ultraviolet?

23. | What temperature, in °C, is a blackbody whose emission spectrum peaks at (a) 300 nm and (b) 3.00 μm?

24. || A 2.0-cm-diameter metal sphere is glowing red, but a spectrum shows that its emission spectrum peaks at an infrared wavelength of 2.0 μm. How much power does the sphere radiate?

25. || A ceramic cube 3.0 cm on each side radiates heat at 630 W. At what wavelength, in μm, does its emission spectrum peak?

Problems

26. || What is the total energy, in MeV, of
    a. A proton traveling at 99% of the speed of light?
    b. An electron traveling at 99% of the speed of light?
    Hint: This problem uses relativity.

27. || What is the velocity, as a fraction of c, of
    a. A proton with 500 GeV total energy?
    b. An electron with 2.0 GeV total energy?
    Hint: This problem uses relativity.

28. || You learned in Chapter 37 that mass has an equivalent amount of energy. What are the energy equivalents in MeV of the rest masses of an electron and a proton?

29. || The factor γ appears in many relativistic expressions. A value $\gamma = 1.01$ implies that relativity changes the Newtonian values by approximately 1% and that relativistic effects can no longer be ignored. At what kinetic energy, in MeV, is $\gamma = 1.01$ for (a) an electron, (b) a proton, and (c) an alpha particle?

30. || The fission process $n + {}^{235}U \rightarrow {}^{236}U \rightarrow {}^{144}Ba + {}^{89}Kr + 3n$ converts 0.185 u of mass into the kinetic energy of the fission products. What is the total kinetic energy in MeV?

31. | An electron in a cathode-ray beam passes between 2.5-cm-long parallel-plate electrodes that are 5.0 mm apart. A 1.0 mT, 2.5-cm-wide magnetic field is perpendicular to the electric field between the plates. If the potential difference between the plates is 150 V, the electron passes through the electrodes without being deflected. If the potential difference across the plates is set to zero, through what angle is the electron deflected as it passes through the magnetic field?

32. | The two 5.0-cm-long parallel electrodes in FIGURE P38.32 are spaced 1.0 cm apart. A proton enters the plates from one end, an equal distance from both electrodes. A potential difference $\Delta V = 500$ V across the electrodes deflects the proton so that it strikes the outer end of the lower electrode. What magnetic field strength and direction will allow the proton to pass through undeflected while the 500 V potential difference is applied? Assume that both the electric and magnetic fields are confined to the space between the electrodes.

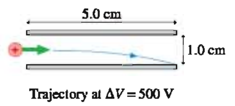

FIGURE P38.32

33. | An unknown charged particle passes without deflection through crossed electric and magnetic fields of strengths 187,500 V/m and 0.125 T, respectively. The particle passes out of the electric field, but the magnetic field continues, and the particle makes a semicircle of diameter 25.05 cm. What is the particle's charge-to-mass ratio? Can you identify the particle?

34. | In one of Thomson's experiments he placed a thin metal foil in the electron beam and measured its temperature rise. Consider a cathode-ray tube in which electrons are accelerated through a 2000 V potential difference, then strike a 10 mg copper foil.
   a. How many electrons strike the foil in 10 s if the foil temperature rises 6.0° C? Assume no loss of energy by radiation or other means.
   b. What is the current of the electron beam?

35. | A neutral lithium atom has three electrons. As you will discover in Chapter 42, two of these electrons form an "inner core," but the third—the valence electron—orbits at much larger radius. From the valence electron's perspective, it is orbiting a spherical ball of charge having net charge $+1e$ (i.e., the three protons in the nucleus and the two inner-core electrons). The energy required to ionize a lithium atom is 5.14 eV. According to Rutherford's nuclear model of the atom, what are the orbital radius and speed of the valence electron?
Hint: Consider the energy needed to remove the electron *and* the force needed to give the electron a circular orbit.

36. | The diameter of an atom is 1.2×10^{-10} m and the diameter of its nucleus is 1.0×10^{-14} m. What percent of the atom's volume is occupied by mass and what percent is empty space?

37. | Balmer discovered the famous formula that bears his name by inspection and trial and error. See if you can discover the formula for each of the following series of wavelengths. Each formula involved an integer n, but, as in the Balmer formula, n may not start with 1.
   a. 125.00, 31.25, 13.89, 7.81, and 5.00 nm.
   b. 375, 900, 1575, 2400, 3375, and 4500 nm.

38. | The diameter of an aluminum atom is approximately 1.2×10^{-10} m. The diameter of the nucleus of an aluminum atom is approximately 8×10^{-15} m. The density of solid aluminum is 2700 kg/m^3.
   a. What is the average density of an aluminum atom?
   b. Your answer to part a was similar to but larger than the density of solid aluminum. This suggests that the atoms in solid aluminum have spaces between them rather than being tightly packed together. What is the average volume per atom in solid aluminum? If this volume is a sphere, what is the radius? What can you conclude about the average spacing between atoms compared to the size of the atoms?
Hint: The volume *per* atom is not the same as the volume *of* an atom.
   c. What is the density of the aluminum nucleus? By what factor is the nuclear density larger than the density of solid aluminum?

39. | The charge-to-mass ratio of a nucleus, in units of e/u, is $q/m = Z/A$. For example, a hydrogen nucleus has $q/m = 1/1 = 1$.
   a. Make a graph of charge-to-mass ratio versus proton number Z for nuclei with $Z = 5, 10, 15, 20, \ldots, 90$. For A, use the average atomic mass shown on the periodic table of elements in Appendix B. Show each of these 18 nuclei as a dot, but don't connect the dots together as a curve.
   b. Describe any trend that you notice in your graph.
   c. What's happening in the nuclei that is responsible for this trend?

40. | If the nucleus is a few fm in diameter, the distance between the centers of two protons must be ≈ 2 fm.
   a. Calculate the repulsive electric force between two protons that are 2.0 fm apart.
   b. Calculate the attractive gravitational force between two protons that are 2.0 fm apart. Could gravity be the force that holds the nucleus together?
   c. Your answers to parts a and b imply that there must be some other force that binds the nucleus together and prevents the protons from pushing each other out. What characteristics of this force can you deduce from the discussion of the atom and the nucleus in this chapter?

41. | In a head-on collision, the closest approach of a 6.24 MeV alpha particle to the center of a nucleus is 6.00 fm. The nucleus is in an atom of what element? Assume the nucleus remains at rest.

42. | Through what potential difference would you need to accelerate an alpha particle, starting from rest, so that it will just reach the surface of a 15-fm-diameter ^{238}U nucleus?

43. | The oxygen nucleus ^{16}O has a radius of 3.0 fm.
   a. With what speed must a proton be fired toward an oxygen nucleus to have a turning point 1.0 fm from the surface? Assume the nucleus remains at rest.
   b. What is the proton's kinetic energy in MeV?

44. | To initiate a nuclear reaction, an experimental nuclear physicist wants to shoot a proton *into* a ^{12}C nucleus. The proton must impact the nucleus with a kinetic energy of 3.00 MeV. The nuclear radius is 2.75 fm, and you can assume the nucleus remains at rest.
   a. With what speed must the proton be fired toward the target?
   b. Through what potential difference must the proton be accelerated from rest to acquire this speed?

45. || The cesium isotope ^{137}Cs, with $Z = 55$, is radioactive and decays by beta decay. A beta particle is observed in the laboratory with a kinetic energy of 300 keV. The nucleus of a ^{137}Cs atom has a diameter of 12.4 fm. With what kinetic energy was the beta particle ejected from the ^{137}Cs nucleus?

Challenge Problems

46. An alpha particle approaches a ^{197}Au nucleus with a speed of 1.50×10^7 m/s. As FIGURE CP38.46 shows, the alpha particle is scattered at a 49° angle at the slower speed of 1.49×10^7 m/s. In what direction does the ^{197}Au nucleus recoil, and with what speed?

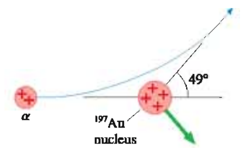

FIGURE CP38.46

47. Physicists first attempted to understand the hydrogen atom by applying the laws of classical physics. Consider an electron of mass m and charge $-e$ in a circular orbit of radius r around a proton of charge $+e$.
    a. Use Newtonian physics to show that the total energy of the atom is $E = -e^2/8\pi\epsilon_0 r$.
    b. Show that the potential energy is -2 times the electron's kinetic energy. This result is called the *virial theorem.*
    c. The minimum energy needed to ionize a hydrogen atom (i.e., to remove the electron) is found experimentally to be 13.6 eV. From this information, what are the electron's speed and the radius of its orbit?
48. Consider an oil droplet of mass m and charge q. We want to determine the charge on the droplet in a Millikan-type experiment. We will do this in several steps. Assume, for simplicity, that the charge is positive and that the electric field between the plates points upward.
    a. An electric field is established by applying a potential difference to the plates. It is found that a field of strength E_0 will cause the droplet to be suspended motionless. Write an expression for the droplet's charge in terms of the suspending field E_0 and the droplet's weight mg.
    b. The field E_0 is easily determined by knowing the plate spacing and measuring the potential difference applied to them. The larger problem is to determine the mass of a microscopic droplet. Consider a mass m falling through viscous medium in which there is a retarding or drag force. For very small particles, the retarding force is given by $F_{drag} = -bv$ where b is a constant and v the droplet's velocity. The sign recognizes that the drag force vector points upward when the droplet is falling (negative v). A falling droplet quickly reaches a constant speed, called the *terminal speed.* Write an expression for the terminal speed v_{term} in terms of m, g, and b.
    c. A spherical object of radius r moving slowly through the air is known to experience a retarding force $F_{drag} = -6\pi\eta r v$ where η is the *viscosity* of the air. Use this and your answer to part b to show that a spherical droplet of density ρ falling with a terminal velocity v_{term} has a radius

$$r = \sqrt{\frac{9\eta v_{term}}{2\rho g}}$$

    d. Oil has a density 860 kg/m^3. An oil droplet is suspended between two plates 1.0 cm apart by adjusting the potential difference between them to 1177 V. When the voltage is removed, the droplet falls and quickly reaches constant speed. It is timed with a stopwatch, and falls 3.00 mm in 7.33 s. The viscosity of air is 1.83×10^{-5} kg/m s. What is the droplet's charge?
    e. How many units of the fundamental electric charge does this droplet possess?
49. A classical atom orbiting at frequency f would emit electromagnetic waves of frequency f because the electron's orbit, seen edge-on, looks like an oscillating electric dipole.
    a. At what radius, in nm, would the electron orbiting the proton in a hydrogen atom emit light with a wavelength of 600 nm?
    b. What is the total mechanical energy of this atom?

STOP TO THINK ANSWERS

Stop to Think 38.1: b. This observation says that all electrons are the same.

Stop to Think 38.2: b. From the right-hand rule with $\vec{v}$ to the right and $\vec{B}$ out of the page.

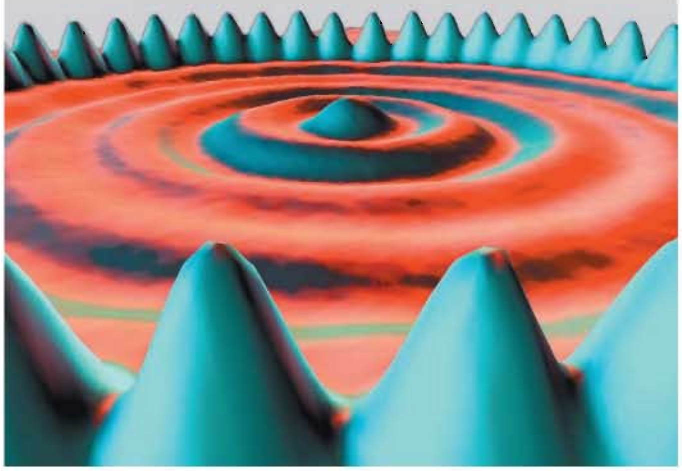
Stop to Think 38.3: 4. Neutral carbon would have six electrons. C^{++} is missing two.

Stop to Think 38.4: 6 protons and 8 neutrons. The number of protons is the atomic number, which is 6. That leaves $14 - 6 = 8$ neutrons.

Stop to Think 38.5: a is emission, b is absorption. All wavelengths in the absorption spectrum are seen in the emission spectrum, but not all wavelengths in the emission spectrum are seen in the absorption spectrum.

39 Quantization

A scanning tunneling microscope image of a "quantum corral" made from 60 iron atoms.



▶ Looking Ahead
The goal of Chapter 39 is to understand the quantization of energy for light and matter. In this chapter you will learn to:

- Understand the photoelectric effect in terms of light quanta.
- Use the photon concept.
- Understand how de Broglie's matter waves lead to the quantization of energy.
- Use Bohr's model of quantization in atoms.
- Calculate energies and wavelengths for hydrogen and hydrogen-like ions.

◀ Looking Back
Many of the ideas in this chapter were introduced in Chapter 25, which is an essential prerequisite for this chapter. Please review:

- Sections 22.2, 22.3, and 22.6 Interference and interferometers.
- Chapter 25 Photons, matter waves, and quantization.
- Section 38.6 Electron volts and Rutherford's nuclear model of the atom.

The picture shown here, called a "quantum corral," was made with a scanning tunneling microscope, a device we'll study in Chapter 41. The image shows the electron density in the vicinity of a circle of 60 iron atoms that have been carefully placed on a plane of carbon. But it's not the circle of electrons gathered around the iron atoms that is most interesting. Notice the circular ripple-like rings in the center of the corral. What you're seeing is an *electron standing wave,* rather like the standing wave on the head of a vibrating drum.

Recall from Chapter 25 that the classical either-or distinction between particles and waves, as useful as it is for macroscopic systems, does not exist in the microscopic world of electrons and atoms. Instead, light and matter exhibit characteristics of *both* particles *and* waves. This new *wave-particle duality* defies our commonsense picture of how things ought to behave. Nonetheless, modern engineering devices, such as *quantum-well lasers,* make explicit use of wave–particle duality.

This chapter will explore two critical ideas: Einstein's introduction of a particle-like nature of light and Bohr's development of a quantum atom. We will begin to think about and describe matter and light in terms of a quantum model rather than classical models. In addition, the ideas in this chapter are the final steps we need before introducing quantum mechanics in Chapter 40.

39.1 The Photoelectric Effect

In 1886, Heinrich Hertz was the first to demonstrate that electromagnetic waves can be artificially generated. By verifying the predictions of Maxwell's electromagnetic theory, Hertz cemented the last blocks of classical physics into place. Yet in one of those ever-present ironies of history, Hertz happened, quite by chance, to discover the very phenomenon that would launch the quantum revolution. He noticed, in the course of his investigations, that a negatively charged electroscope could be discharged by shining ultraviolet light on it.

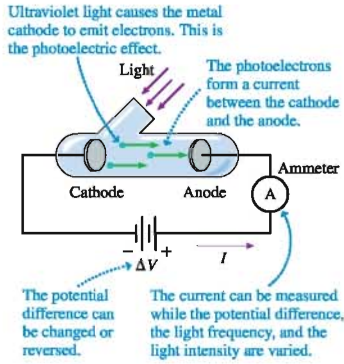
Hertz's observation caught the attention of J. J. Thomson, who inferred that the ultraviolet light was causing the electrode to emit negative charges, thus restoring itself to electric neutrality. In 1899, Thomson showed that the emitted charges were electrons. The emission of electrons from a substance due to light striking its surface came to be called the **photoelectric effect.** The emitted electrons are often called *photoelectrons* to indicate their origin, but they are identical in every respect to all other electrons.

Although this discovery might seem to be a minor footnote in the history of science, it soon became a, or maybe *the,* pivotal event that opened the door to new ideas. We will look at the photoelectric effect in a fair bit of detail. Our goals are to understand how classical physics was unable to explain the details of such a simple experiment and to recognize the startling new concept introduced by Einstein.

Characteristics of the Photoelectric Effect

It was not the discovery itself that dealt the fatal blow to classical physics, but the specific characteristics of the photoelectric effect found around 1900 by one of Hertz's students, Phillip Lenard. Lenard built a glass tube, shown in FIGURE 39.1, with two facing electrodes and a window. After removing the air from the tube, so that electrons could move freely from one electrode to the other, he allowed light to shine on the cathode.

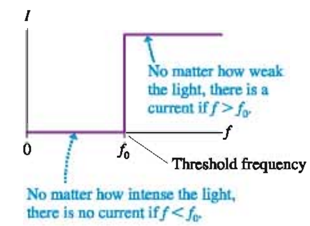
FIGURE 39.1 Lenard's experimental device to study the photoelectric effect.



Lenard found a counterclockwise current (clockwise flow of electrons) through the ammeter whenever ultraviolet light was shining on the cathode. There are no junctions in this circuit, so the current must be the same all the way around the loop. The current in the space between the cathode and the anode consists of electrons moving freely through space (i.e., not inside a wire) at the *same rate* (same number of electrons per second) as the current in the wire. There is no current if the electrodes are in the dark, so electrons don't spontaneously leap off the cathode. Instead, the light causes electrons to be ejected from the cathode at a steady rate.

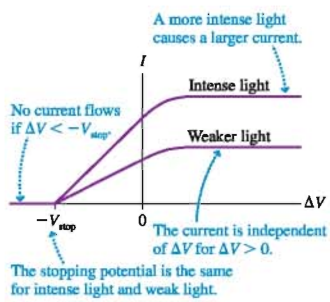
Lenard used a battery to establish an adjustable potential difference ΔV between the two electrodes. He then studied how the current I varied as the potential difference and the light's frequency and intensity were changed. Lenard made the following observations.

FIGURE 39.2 The photoelectric current as a function of the light frequency f.



1. The current I is directly proportional to the light intensity. If the light intensity is doubled, the current also doubles.
2. The current appears without delay when the light is applied. To Lenard, this meant within the ≈ 0.1 s with which his equipment could respond. Later experiments showed that the current begins in less than 1 ns.
3. Photoelectrons are emitted *only* if the light frequency f exceeds a **threshold frequency** f_0. This is shown in the graph of FIGURE 39.2.
4. The value of the threshold frequency f_0 depends on the type of metal from which the cathode is made.
5. If the potential difference ΔV is positive (anode positive with respect to the cathode), the current does not change as ΔV is increased. If ΔV is made negative (anode negative with respect to the cathode), by reversing the battery, the current decreases until, at some voltage $\Delta V = -V_{stop}$ the current reaches zero. The value of V_{stop} is called the **stopping potential.** This behavior is shown in FIGURE 39.3.
6. The value of V_{stop} is the same for both weak light and intense light. A more intense light causes a larger current, as Figure 39.3 shows, but in both cases the current ceases when $\Delta V = -V_{stop}$.

FIGURE 39.3 The photoelectric current as a function of the battery potential.



NOTE ▶ We're defining V_{stop} to be a *positive* number. The potential difference that stops the electrons is $\Delta V = -V_{stop}$, with an explicit minus sign. ◀

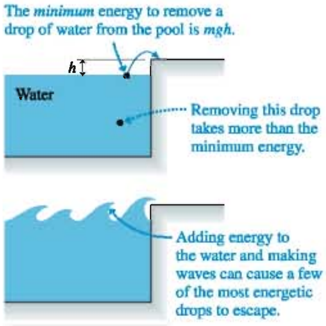


FIGURE 39.4 A swimming pool analogy of electrons in a metal.

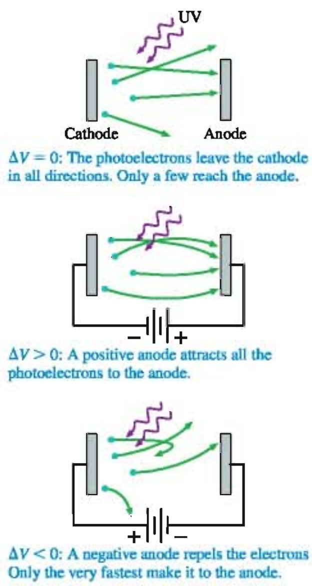
TABLE 39.1 The work function for some of the elements

Element	E_0 (eV)
Potassium	2.30
Sodium	2.75
Aluminum	4.28
Tungsten	4.55
Copper	4.65
Iron	4.70
Gold	5.10

FIGURE 39.5 The photoelectron current depends on the anode potential.



Classical Interpretation of the Photoelectric Effect

The mere existence of the photoelectric effect is not, as is sometimes assumed, a difficulty for classical physics. You learned in Chapter 26 that electrons are the charge carriers in a metal and move around freely inside like a sea of negatively charged particles. The electrons are bound inside the metal and do not spontaneously spill out of an electrode at room temperature. But a piece of metal heated to a sufficiently high temperature *does* emit electrons in a process called **thermal emission.** The electron gun in an older television or computer display terminal starts with the thermal emission of electrons from a hot tungsten filament.

A useful analogy, shown in FIGURE 39.4, is the water in a swimming pool. Water molecules do not spontaneously leap out of the pool if the water is calm. To remove a water molecule, you must do *work* on it to lift it upward, against the force of gravity, to the edge of the pool. A minimum energy is needed to extract a water molecule, namely the energy needed to lift a molecule that is right at the surface. Removing a water molecule that is deeper requires more than the minimum energy. People playing in the pool add energy to the water, causing waves. If sufficient energy is added, a small fraction of the water molecules may gain enough energy to splash over the edge and leave the pool.

Similarly, a *minimum* energy is needed to free an electron from a metal. To extract an electron, you would need to exert a force on it and pull it (i.e., do *work* on it) until its speed is large enough to escape. The minimum energy E_0 needed to free an electron is called the **work function** of the metal. Some electrons, like the deeper water molecules, may require more energy than E_0 to escape, but all will require *at least* E_0. Different metals have different work functions; Table 39.1 provides a short list. Notice that work functions are given in electron volts.

Heating a metal, like splashing in the pool, increases the thermal energy of the electrons. At a sufficiently high temperature, the kinetic energy of a small percentage of the electrons may exceed the work function. These electrons can "make it out of the pool" and leave the metal. In practice, there are only a few elements, such as tungsten, for which thermal emission can become significant before the metal melts!

Suppose we could raise the temperature of only the electrons, not the crystal lattice. One possible way to do this is to shine a light wave on the surface. Because electromagnetic waves are absorbed by the conduction electrons, not by the positive ions, the light wave heats only the electrons. Eventually the electrons' energy is transferred to the crystal lattice, via collisions, but if the light is sufficiently intense, the *electron temperature* may be significantly higher than the temperature of the metal. In 1900, it was plausible to think that an intense light source could cause the thermal emission of electrons without melting the metal.

The Stopping Potential

Photoelectrons leave the cathode with kinetic energy. An electron with energy E_{elec} inside the metal loses energy ΔE as it escapes, so it emerges as a photoelectron with kinetic energy $K = E_{elec} - \Delta E$. The work function energy E_0 is the *minimum* energy needed to remove an electron, so the *maximum* possible kinetic energy of a photoelectron is

$$K_{max} = E_{elec} - E_0 \tag{39.1}$$

The photoelectrons, after leaving the cathode, move out in all directions. Some electrons reach the anode, creating a measurable current, but many do not. However, as FIGURE 39.5 shows:

- A positive anode attracts *all* of the photoelectrons to the anode. Once all electrons reach the anode, a further increase in ΔV does not cause any further increase in the current I. That is why the graph lines become horizontal on the right side of Figure 39.3.

- A negative anode repels the electrons. However, photoelectrons leaving the cathode with sufficient kinetic energy can still reach the anode. The current steadily decreases as the anode voltage becomes increasingly negative until, at the stopping potential, *all* electrons are turned back and the current ceases. This was the behavior observed on the left side of Figure 39.3.

Let the cathode be the point of zero potential energy, as shown in FIGURE 39.6. An electron emitted from the cathode with kinetic energy K_i has initial total energy

$$E_i = K_i + U_i = K_i + 0 = K_i$$

When the electron reaches the anode, which is at potential ΔV relative to the cathode, it has potential energy $U = q\Delta V = -e\Delta V$ and final total energy

$$E_f = K_f + U_f = K_f - e\Delta V$$

From conservation of energy, $E_f = E_i$, the electron's final kinetic energy is

$$K_f = K_i + e\Delta V \tag{39.2}$$

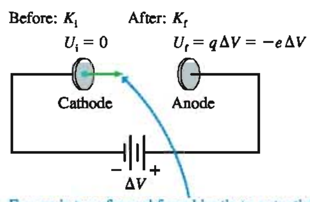


FIGURE 39.6 Energy is conserved.

The electron speeds up ($K_f > K_i$) if ΔV is positive. The electron slows down if ΔV is negative, but it still reaches the anode ($K_f > 0$) if K_i is large enough.

An electron with initial kinetic energy K_i will stop just as it reaches the anode if the potential difference is $\Delta V = -K_i/e$. The potential difference that turns back the very fastest electrons, those with $K = K_{max}$, and thus stops the current is

$$\Delta V_{\text{stop fastest electrons}} = -\frac{K_{max}}{e}$$

By definition, the potential difference that causes the electron current to cease is $\Delta V = -V_{stop}$, where V_{stop} is the stopping potential. The stopping potential is

ActivPhysics ONLINE 17.3

$$V_{stop} = \frac{K_{max}}{e} \tag{39.3}$$

Thus the stopping potential tells us the maximum kinetic energy of the photoelectrons.

EXAMPLE 39.1 The classical photoelectric effect

A photoelectric-effect experiment is performed with an aluminum cathode. An electron inside the cathode has a speed of 1.5×10^6 m/s. If the potential difference between the anode and cathode is -2.00 V, what is the highest possible speed with which this electron could reach the anode?

MODEL Energy is conserved.

SOLVE If the electron escapes with the maximum possible kinetic energy, its kinetic energy at the anode will be given by Equation 39.2 with $\Delta V = -2.00$ V. The electron's initial kinetic energy is

$$E_{elec} = \frac{1}{2}mv^2 = \frac{1}{2}(9.11 \times 10^{-31}\text{ kg})(1.5 \times 10^6\text{ m/s})^2$$
$$= 1.025 \times 10^{-18}\text{ J} = 6.41\text{ eV}$$

Its maximum possible kinetic energy as it leaves the cathode is

$$K_i = K_{max} = E_{elec} - E_0 = 2.13\text{ eV}$$

where $E_0 = 4.28$ eV is the work function of aluminum. Thus the kinetic energy at the anode, given by Equation 39.2, is

$$K_f = K_i + e\Delta V = 2.13\text{ eV} - (e)(2.00\text{ V}) = 0.13\text{ eV}$$

Notice that the electron loses 2.00 eV of *energy* as it moves through the *potential* difference of -2.00 V, so we can compute the final kinetic energy in eV without having to convert to joules. However, we must convert K_f to joules to find the final speed:

$$K_f = \frac{1}{2}mv_f^2 = 0.13\text{ eV} = 2.1 \times 10^{-20}\text{ J}$$

$$v_f = \sqrt{\frac{2K_f}{m}} = 2.1 \times 10^5\text{ m/s}$$

Limits of the Classical Interpretation

A classical analysis based on the thermal emission of electrons from a metal has provided a possible explanation of observations 1 and 5 above. But nothing in this explanation suggests that there should be a threshold frequency, as Lenard found. If a weak intensity at a frequency just slightly above f_0 can generate a current, why can't a strong intensity at a frequency just slightly below f_0 do so?

And what about Lenard's observation that the current starts instantly? If the photoelectrons are due to thermal emission, it should take some time for the light to raise the electron temperature sufficiently high for some to escape. In fact, fairly straightforward calculations show that, for a light of modest intensity, it should take several minutes before charge starts flowing! The experimental evidence was in sharp disagreement.

And last, more intense light would be expected to heat the electrons to a higher temperature. Doing so should increase the maximum kinetic energy of the photoelectrons and thus should increase the stopping potential V_{stop}. But as Lenard found, the stopping potential is the same for strong light as it is for weak light.

Although the mere presence of photoelectrons did not seem surprising, classical physics was unable to explain the observed behavior of the photoelectrons. The threshold frequency and the instant current seemed particularly anomalous.

39.2 Einstein's Explanation

FIGURE 39.7 A young Einstein.

Albert Einstein, seen in **FIGURE 39.7**, was a little-known young man of 26 in 1905. He had recently graduated from the Polytechnic Institute in Zurich, Switzerland, with the Swiss equivalent of a Ph.D. in physics. Although his mathematical brilliance was recognized, his overall academic record was mediocre. Rather than pursue an academic career, Einstein took a job with the Swiss Patent Office in Bern. This was a fortuitous choice because it provided him with plenty of spare time to think about physics in his own unique way.

In 1905, Einstein published his initial paper on the theory of relativity, the subject for which he is most well known to the general public. He also published another paper, on the nature of light, and it is this second paper in which we are most interested. In it Einstein offered an exceedingly simple but amazingly bold idea to explain Lenard's photoelectric-effect data.

A few years earlier, in 1900, the German physicist Max Planck had been trying to understand the details of the rainbow-like black-body spectrum of light emitted by a glowing hot object. As we noted in the preceding chapter, this problem didn't yield to a classical physics analysis, but Planck found that he could calculate the spectrum perfectly if he made an unusual assumption. The atoms in a solid vibrate back and forth around their equilibrium positions with frequency f. You learned in Chapter 14 that the energy of a simple harmonic oscillator depends on its amplitude and can have *any* possible value. But to predict the spectrum correctly, Planck had to assume that the oscillating atoms are *not* free to have any possible energy. Instead, the energy of an atom vibrating with frequency f has to be one of the specific energies $E = 0, hf, 2hf, 3hf, \ldots$, where h is a constant. That is, the vibration energies are *quantized*.

Planck was able to determine the value of the constant h by comparing his calculations of the spectrum to experimental measurements. The constant that he introduced into physics is now called **Planck's constant**. Its contemporary value is

$$h = 6.63 \times 10^{-34}\ \mathrm{J\,s} = 4.14 \times 10^{-15}\ \mathrm{eV\,s}$$

The first value, with SI units, is the proper one for most calculations, but you will find the second to be useful when energies are expressed in eV.

Einstein was the first to take Planck's quantization idea seriously. He went even further and suggested that **electromagnetic radiation itself is quantized!** That is, light is not really a continuous wave but, instead, arrives in small packets or bundles of energy. Einstein called each packet of energy a **light quantum,** and he postulated that the energy of one light quantum is directly proportional to the frequency of the light. That is, each quantum of light has energy

$$E = hf \tag{39.4}$$

where h is Planck's constant and f is the frequency of the light.

The idea of light quanta is subtle, so let's look at an analogy with raindrops. Although we often think of water as a continuous fluid, such as water in a beaker, rain consists of water that falls in discrete packets called raindrops. Raindrops are analogous to quanta of light. A downpour has a torrent of raindrops, but in a light shower the drops are few. The difference between "intense" rain and "weak" rain is the *rate* at which the drops arrive. An intense rain makes a continuous noise on the roof, so you are not aware of the individual drops, but the individual drops become apparent during a light rain.

Similarly, a great number of light quanta arrive each second when the light is intense, but very weak light consists of only a few quanta per second. And just as raindrops come in different sizes, with larger-mass drops having larger kinetic energy, higher-frequency light quanta have a larger amount of energy. Although this analogy is not perfect, it does provide a useful mental picture of light quanta arriving at a surface.

For most light sources, the individual quanta are no more discernible than the individual raindrops in a downpour.

EXAMPLE 39.2 The energy of a light quantum

What is the energy of one quantum of light having a wavelength of 500 nm?

SOLVE Light with a wavelength of 500 nm has frequency

$$f = \frac{v}{\lambda} = \frac{c}{\lambda} = \frac{3.00 \times 10^8 \text{ m/s}}{500 \times 10^{-9} \text{ m}} = 6.00 \times 10^{14} \text{ Hz}$$

One light quantum has energy

$$E = hf = 3.98 \times 10^{-19} \text{ J} = 2.49 \text{ eV}$$

ASSESS Because 500 nm is a typical wavelength for visible light (it would be perceived as green light), you can see that the electron volt is an energy unit of more appropriate size than the joule.

Einstein's Postulates

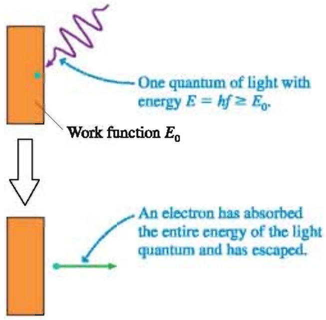
Einstein framed three postulates about light quanta and their interaction with matter:

1. Light of frequency f consists of discrete quanta, each of energy $E = hf$. Each photon travels at the speed of light c.
2. Light quanta are emitted or absorbed on an all-or-nothing basis. A substance can emit 1 or 2 or 3 quanta, but not 1.5. Similarly, an electron in a metal cannot absorb half a quantum but, instead, only an integer number.
3. A light quantum, when absorbed by a metal, delivers its entire energy to *one* electron.

NOTE ▶ These three postulates—that light comes in chunks, that the chunks cannot be divided, and that the energy of one chunk is delivered to one electron—are crucial for understanding the new ideas that will lead to quantum physics. They are completely at odds with the concepts of classical physics, where energy can be continuously divided and shared, so they deserve careful thought. ◀

Let's look at how Einstein's postulates apply to the photoelectric effect. If Einstein is correct, the light of frequency f shining on the metal is a torrent of light quanta, each of energy hf. Each quantum is absorbed by *one* electron, giving that electron an energy $E_{elec} = hf$. This leads us to several interesting conclusions:

FIGURE 39.8 The creation of a photoelectron.



1. An electron that has just absorbed a quantum of light energy has $E_{elec} = hf$. (The electron's thermal energy at room temperature is so much less than hf that we can neglect it.) FIGURE 39.8 shows that this electron can escape from the metal, becoming a photoelectron, if

$$E_{elec} = hf \geq E_0 \tag{39.5}$$

In other words, there is a *threshold frequency*

$$f_0 = \frac{E_0}{h} \tag{39.6}$$

for the ejection of photoelectrons. If f is less than f_0, even by just a small amount, none of the electrons will have sufficient energy to escape no matter how intense the light. But even very weak light with $f \geq f_0$ will give a few electrons sufficient energy to escape **because each light quantum delivers all of its energy to one electron.** This threshold behavior is exactly what Lenard observed.

NOTE ▶ The threshold frequency is directly proportional to the work function. Metals with large work functions, such as iron, copper, and gold, exhibit the photoelectric effect only when illuminated by high-frequency ultraviolet light. Photoemission occurs with lower-frequency visible light for metals with smaller values of E_0, such as sodium and potassium.

2. A more intense light delivers a larger number of light quanta to the surface. These quanta eject a larger number of photoelectrons and cause a larger current, exactly as observed.
3. There is a distribution of kinetic energies, because different photoelectrons require different amounts of energy to escape, but the *maximum* kinetic energy is

$$K_{max} = E_{elec} - E_0 = hf - E_0 \tag{39.7}$$

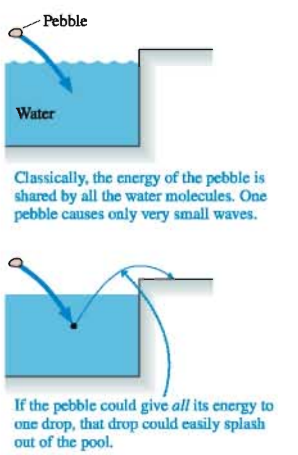
As we noted in Equation 39.3, the stopping potential V_{stop} is directly proportional to K_{max}. Einstein's theory predicts that the stopping potential is related to the light frequency by

$$V_{stop} = \frac{K_{max}}{e} = \frac{hf - E_0}{e} \tag{39.8}$$

The stopping potential does *not* depend on the intensity of the light. Both weak light and intense light will have the same stopping potential, as Lenard had observed but which could not previously be explained.

4. If each light quantum transfers its energy hf to just one electron, that electron *immediately* has enough energy to escape. The current should begin instantly, with no delay, exactly as Lenard had observed.

FIGURE 39.9 A pebble transfers energy to the water.



Using the swimming pool analogy again, FIGURE 39.9 shows a pebble being thrown into the pool. The pebble increases the energy of the water, but the increase is shared among all the molecules in the pool. The increase in the water's energy is barely enough to make ripples, not nearly enough to splash water out of the pool. But suppose *all* the pebble's energy could go to *one drop* of water that didn't have to share it. That one drop of water would easily have enough energy to leap out of the pool. Einstein's hypothesis that a light quantum transfers all its energy to one electron is equivalent to the pebble transferring all its energy to one drop of water.

A Prediction

Not only do Einstein's hypotheses explain all of Lenard's observations, they also make a new prediction. According to Equation 39.8, the stopping potential should be a linearly increasing function of the light's frequency f. We can rewrite Equation 39.8 in terms of the threshold frequency $f_0 = E_0/h$ as

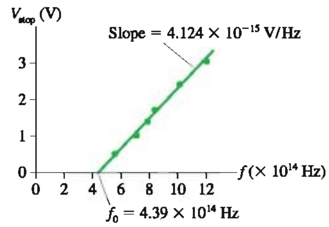
$$V_{stop} = \frac{h}{e}(f - f_0) \qquad (39.9)$$

A graph of the stopping potential V_{stop} versus the light frequency f should start from zero at $f = f_0$, then rise linearly with a slope of h/e. In fact, the slope of the graph provides a way to measure Planck's constant h.

Lenard had not measured the stopping potential for different frequencies, so Einstein offered this as an untested prediction of his postulates. Robert Millikan, who was well known for his oil-drop experiment to measure e, took up the challenge. Some of Millikan's data for a cesium cathode are shown in FIGURE 39.10. As you can see, Einstein's prediction of a linear relationship between f and V_{stop} was confirmed.

Millikan measured the slope of his graph and multiplied it by the value of e (which he had measured a few years earlier in the oil-drop experiment) to find h. His value agreed with the value that Planck had determined in 1900 from an entirely different experiment. Light quanta, whether physicists liked the idea or not, were real.

FIGURE 39.10 A graph of Millikan's data for the stopping potential as the light frequency is varied.



EXAMPLE 39.3 The photoelectric threshold frequency

What are the threshold frequencies and wavelengths for photoemission from sodium and from aluminum?

SOLVE Table 39.1 gives the sodium work function as $E_0 = 2.75$ eV. Aluminum has $E_0 = 4.28$ eV. We can use Equation 39.6, with h in units of eV s, to calculate

$$f_0 = \frac{E_0}{h} = \begin{cases} 6.64 \times 10^{14}\text{ Hz} & \text{sodium} \\ 10.34 \times 10^{14}\text{ Hz} & \text{aluminum} \end{cases}$$

These frequencies are converted to wavelengths with $\lambda = c/f$, giving

$$\lambda = \begin{cases} 452\text{ nm} & \text{sodium} \\ 290\text{ nm} & \text{aluminum} \end{cases}$$

ASSESS The photoelectric effect can be observed with sodium for $\lambda < 452$ nm. This includes blue and violet visible light but not red, orange, yellow, or green. Aluminum, with a larger work function, needs ultraviolet wavelengths $\lambda < 290$ nm.

EXAMPLE 39.4 Maximum photoelectron speed

What is the maximum photoelectron speed if sodium is illuminated with light of 300 nm?

SOLVE The light frequency is $f = c/\lambda = 1.00 \times 10^{15}$ Hz, so each light quantum has energy $hf = 4.14$ eV. The maximum kinetic energy of a photoelectron is

$$K_{max} = hf - E_0 = 4.14\text{ eV} - 2.75\text{ eV} = 1.39\text{ eV}$$
$$= 2.22 \times 10^{-19}\text{ J}$$

Because $K = \frac{1}{2}mv^2$, where m is the electron's mass, not the mass of the sodium atom, the maximum speed of a photoelectron leaving the cathode is

$$v_{max} = \sqrt{\frac{2K_{max}}{m}} = 6.99 \times 10^5\text{ m/s}$$

Note that we had to convert K_{max} to SI units of J before calculating a speed in m/s.

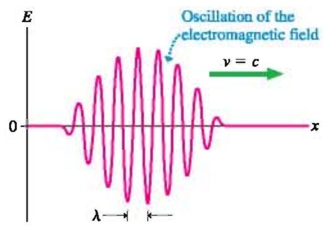
STOP TO THINK 39.1 The work function of metal A is 3.0 eV. Metals B and C have work functions of 4.0 eV and 5.0 eV, respectively. Ultraviolet light shines on all three metals, creating photoelectrons. Rank in order, from largest to smallest, the stopping potential for A, B, and C.

39.3 Photons

Einstein was awarded the Nobel prize in 1921 not for his theory of relativity, as many suppose, but for his explanation of the photoelectric effect. Although Planck had made the first suggestion, it was Einstein who showed convincingly that energy is quantized and that light, even though it exhibits interference, comes in some kind of particle-like packets of energy. These fundamental units of light energy were later given the name **photons.**

But just what are photons? Although particle-like, they clearly do not mesh with the classical idea of a particle. A classical particle, when faced with Young's double-slit apparatus, would go through one hole or the other. If light consisted of classical particles, we would see two bright spots on the screen. Instead, we see interference fringes behind a double slit. We even observed, in Chapter 25, that the interference pattern can be built up photon by photon if the light intensity is very low. This behavior indicates that a photon must, in some sense, go through *both* slits and interfere with itself! Photons seem to be both wave-like *and* particle-like at the same time.

FIGURE 39.11 A wave packet has wave-like and particle-like properties.



Photons are sometimes visualized as **wave packets.** The electromagnetic wave shown FIGURE 39.11 has a wavelength and a frequency, yet it is also discrete and fairly localized. But this cannot be exactly what a photon is because a wave packet would take a finite amount of time to be emitted or absorbed. This is contrary to much evidence that the entire photon is emitted or absorbed in a single instant; there is no point in time at which the photon is "half absorbed." The wave packet idea, although useful, is still too classical to represent a photon.

The bottom line is that there simply is no "true" mental representation of a photon. Analogies such as raindrops or wave packets can be useful, but none is perfectly accurate. We can detect photons, measure the properties of photons, and put photons to practical use, but the ultimate nature of the photon remains a mystery. To paraphrase Gertrude Stein, "A photon is a photon is a photon."

Photodectors based on silicon can be triggered by photons with energy as low as 1.1 eV, corresponding to a wavelength in the infrared. The light-sensing chip in a digital camera can detect the infrared signal given off by a remote control. Press a button on your remote control, aim it at your digital camera, and snap a picture. The picture will clearly show the infrared emitted by the remote, even though this signal is invisible to your eye.

The Photon Rate

Light, in the raindrop analogy, consists of a stream of photons. For monochromatic light of frequency f, N photons have a total energy $E_{\text{light}} = Nhf$. We are usually more interested in the *power* of the light, or the rate (in joules per second, or watts) at which the light energy is delivered. The power is

$$P = \frac{dE_{\text{light}}}{dt} = \frac{dN}{dt}hf = Rhf \tag{39.10}$$

where $R = dN/dt$ is the *rate* at which photons arrive or, equivalently, the number of photons per second.

EXAMPLE 39.5 The photon rate in a laser beam

The 1.0 mW light beam of a helium-neon laser ($\lambda = 633$ nm) shines on a screen. How many photons strike the screen each second?

SOLVE The light-beam power, or energy delivered per second, is $P = 1.0\text{ mW} = 0.0010\text{ J/s}$. This is a realistic value. The frequency of the light is $f = c/\lambda = 4.74 \times 10^{14}$ Hz. The number of photons striking the screen per second, which is the *rate* of arrival of photons, is

$$R = \frac{P}{hf} = 3.2 \times 10^{15} \text{ photons per second}$$

ASSESS That is a lot of photons per second. No wonder we are not aware of individual photons!

Photodetectors

Modern photodetectors are descendants of the photoelectric effect. These range from simple "electric eyes" to the detector array in a video camera. Most detectors use what is called a *photodiode* in which the photoelectrons are emitted internally in a semiconductor. Even so, they still have a threshold frequency, a stopping potential, and other attributes of the photoelectric effect.

Very low light levels can be detected photon by photon with a device called a *photomultiplier tube*, or PMT. FIGURE 39.12a shows that a PMT consists of a cathode, an anode, and a number of intermediate electrodes sealed inside an evacuated glass tube. The cathode is coated with a low-work-function material, allowing it to respond to most visible wavelengths of light. The cathode is at a fairly high negative voltage and the anode, at the other end, is at essentially zero volts. Steadily descending potentials are applied to the intermediate electrodes.

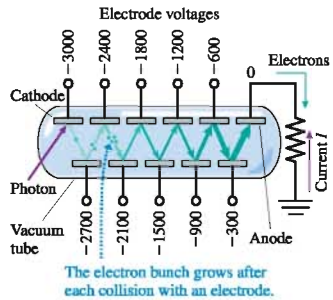
A photon of light ejects a photoelectron from the cathode. The electric field between the cathode and the first intermediate electrode accelerates that electron through a potential difference of about 300 V, and it then strikes this electrode at high speed. When a fast electron collides with a metal surface, it can kick out two or three other electrons called *secondary electrons*. The secondary electrons of the first electrode are accelerated to the second electrode, where they kick out more electrons. These are accelerated to the third electrode, where they kick out yet more electrons, and so on. There is a chain-reaction *multiplication* of electrons—1, 2, 4, 8, 16, . . . — as they move from the cathode toward the anode. For a typical PMT, a single photon at the cathode causes an electron bunch with 10^6 or 10^7 electrons to arrive at the anode.

The electrons are collected by the anode and flow through a resistor. Because these are negative charge carriers, we would say that a current pulse I travels upward through the resistor. This creates a *negative* voltage across the resistor, $\Delta V = IR$, for the length of time that the current lasts. FIGURE 39.12b, an actual measurement, shows a pulse generated by a single photon. The horizontal scale is 0.2 ns/division and the vertical scale is 20 millivolts (mV)/division. You can see that the width of the pulse is $\approx$0.3 ns and its height (measured downward from the baseline) is $\approx$120 mV $=$ 0.12 V. This is not a large voltage, even after the multiplication, but it is a voltage easily detected with modern electronics.

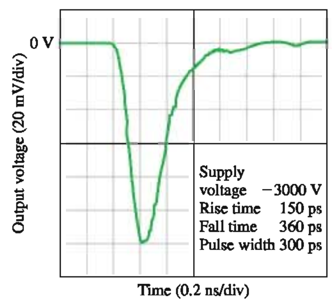
NOTE ▶ The 0.3 ns pulse duration is *not* an indication of the duration of a photon. The photon absorption is instantaneous, but as the electron bunch grows in size, the electron-electron repulsion causes the bunch to spread out some. The observed pulse width is an artifact of the PMT, not a characteristic of the photon. ◀

FIGURE 39.12 A photomultiplier tube can detect individual photons.

(a) A photomultiplier tube



(b) The output signal from a single photon



STOP TO THINK 39.2 The intensity of a beam of light is increased but the light's frequency is unchanged. Which one (or perhaps more than one) of the following is true?

a. The photons travel faster.
b. Each photon has more energy.
c. The photons are larger.
d. There are more photons per second.

39.4 Matter Waves and Energy Quantization

Prince Louis-Victor de Broglie was a French graduate student in 1924. It had been 19 years since Einstein had shaken the world of physics by blurring the distinction between a particle and a wave. As de Broglie thought about these issues, it seemed that nature should have some kind of symmetry. If light waves could have a

particle-like nature, why shouldn't material particles have some kind of wave-like nature? In other words, could **matter waves** exist?

With no experimental evidence to go on, de Broglie reasoned by analogy with Einstein's equation $E = hf$ for the photon and with some of the ideas of his theory of relativity. The details need not concern us, but they led de Broglie to postulate that *if* a material particle of momentum $p = mv$ has a wave-like nature, then its wavelength must be given by

$$\lambda = \frac{h}{p} = \frac{h}{mv} \tag{39.11}$$

where h is Planck's constant. This is called the **de Broglie wavelength.**

EXAMPLE 39.6 The de Broglie wavelength of an electron

What is the de Broglie wavelength of a 1.0 eV electron?

SOLVE An electron with 1.0 eV $= 1.6 \times 10^{-19}$ J of kinetic energy has speed

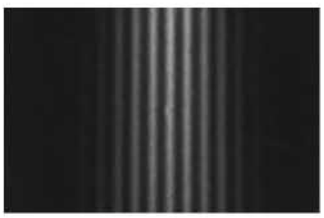
$$v = \sqrt{\frac{2K}{m}} = 5.9 \times 10^5 \text{ m/s}$$

Although fast by macroscopic standards, this is a slow electron because it gains this speed by accelerating through a potential difference of a mere 1 V. Its de Broglie wavelength is

$$\lambda = \frac{h}{mv} = 1.2 \times 10^{-9} \text{ m} = 1.2 \text{ nm}$$

ASSESS The electron's wavelength is small, but it is larger than the wavelengths of x rays and larger than the approximately 10^{-10} m spacing of atoms in a crystal.

FIGURE 39.13 A double-slit interference pattern created with electrons.

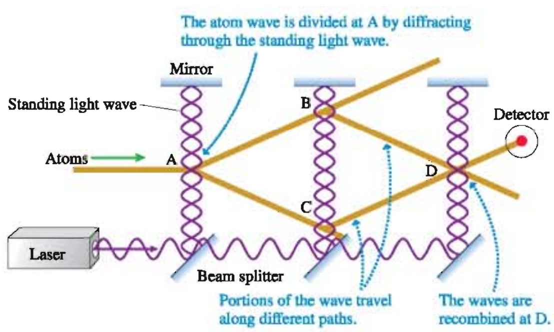


What would it mean for matter—an electron or a proton or a baseball—to have a wavelength? Would it obey the principle of superposition? Would it exhibit interference and diffraction? These are questions we examined in Chapter 25, where we found that, indeed, matter *does* exhibit interference. For example, **FIGURE 39.13** shows the intensity pattern recorded after 50 keV electrons passed through two slits separated by 1.0 μm. The pattern is clearly a double-slit interference pattern, and the spacing of the fringes is exactly as predicted for a wavelength given by de Broglie's formula. Because the electron beam was weak, with one electron at a time passing through the apparatus, it would appear that each electron somehow went through both slits, then recombined to interfere with itself!

Electrons are fundamental subatomic particles. Perhaps subatomic particles have wave-like aspects, but what about entire atoms, aggregates of many fundamental particles? Amazing as it seems, research during the 1980s demonstrated that whole atoms, and even molecules, can produce interference patterns.

FIGURE 39.14 shows an *atom interferometer.* You learned in Chapter 22 that an interferometer, such as the Michelson interferometer, works by dividing a wave front into

FIGURE 39.14 An atom interferometer.



two waves, sending the two waves along separate paths, then recombining them. For light waves, wave division can be accomplished by sending light through the *periodic* slits in a diffraction grating. In an atom interferometer, the atom's matter wave is divided by sending atoms through the *periodic* intensity of a standing light wave.

You can see in the figure that a laser creates three parallel *standing waves* of light, each with nodes spaced a distance $\lambda/2$ apart. The wavelength is chosen so that the light waves exert small forces on an atom in the laser beam. Because the intensity along a standing wave alternates between maximum at the antinodes and zero intensity at the nodes, an atom crossing the laser beam experiences a *periodic* force field. A particle-like atom would be deflected by this periodic force, but a wave is *diffracted.* After being diffracted by the first standing wave at A, an atom is, in some sense, traveling toward both point B *and* point C.

The second standing wave diffracts the atom waves again at points B and C, directing them toward D where, with a third diffraction, they are recombined after having traveled along different paths. Depending on the phases of the waves as they recombine, the detector sometimes records atoms (constructive interference) but at other times does not (destructive interference). Altering one of the paths, such as by applying an electric field in the region around B but not around C, shifts the phases of the atom waves and causes the detector to record interference fringes.

The atom interferometer is fascinating because it completely inverts everything we previously learned about interference and diffraction. The scientists who studied the wave nature of light during the 19th century aimed light (a wave) at a diffraction grating (a periodic structure of matter) and found that it diffracted. Now we aim atoms (matter) at a standing wave (a periodic structure of light) and find that the atoms diffract. The roles of light and matter have been reversed!

Quantization of Energy

De Broglie considered a matter wave to be a traveling wave. But suppose that a "particle" of matter is *confined* to a small region of space and cannot travel? How do the wave-like properties manifest themselves?

This is the problem of "a particle in a box" that we looked at in Chapter 25. We will briefly summarize that discussion. FIGURE 39.15 shows a particle of mass m moving in one dimension as it bounces back and forth with speed v between the ends of a box of length L. We'll call this a *one-dimensional box;* its width isn't relevant.

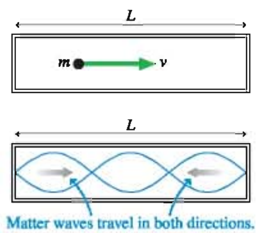


FIGURE 39.15 A particle in a box creates a standing de Broglie wave as it reflects back and forth.

A wave, if it reflects back and forth between two fixed points, sets up a standing wave. You learned in Chapter 21 that a standing wave of length L *must* have a wavelength given by

$$\lambda_n = \frac{2L}{n} \qquad n = 1, 2, 3, 4, \ldots \qquad (39.12)$$

If the confined particle has wave-like properties, it should satisfy both Equation 39.12 *and* the de Broglie relationship $\lambda = h/mv$. That is, a particle in a box should obey the relationship

$$\lambda = \frac{h}{mv} = \frac{2L}{n}$$

This can be true only if the particle's speed is

$$v_n = n\left(\frac{h}{2Lm}\right) \qquad n = 1, 2, 3, \ldots \qquad (39.13)$$

In other words, the particle cannot bounce back and forth with just any speed. Rather, it can have *only* those specific speeds v_n, given by Equation 39.13, for which the de Broglie wavelength creates a standing wave in the box.

Thus the particle's energy, which is purely kinetic energy, is

$$E_n = \frac{1}{2}mv_n^2 = n^2\frac{h^2}{8mL^2} \qquad n = 1, 2, 3, \ldots \tag{39.14}$$

De Broglie's hypothesis about the wave-like properties of matter leads us to the remarkable conclusion that **the energy of a confined particle is quantized.** The energy of the particle in the box can be $1(h^2/8mL^2)$, or $4(h^2/8mL^2)$, or $9(h^2/8mL^2)$, but it *cannot* have an energy between these values.

The possible values of the particle's energy are called **energy levels,** and the integer n that characterizes the energy levels is called the **quantum number.** The quantum number can be found by counting the antinodes, just as you learned to do for standing waves on a string. The standing wave shown in Figure 39.15 is $n = 3$, thus its energy is E_3.

We can rewrite Equation 39.14 in the useful form

$$E_n = n^2E_1 \tag{39.15}$$

where

$$E_1 = \frac{h^2}{8mL^2} \tag{39.16}$$

is the **fundamental quantum of energy** for a particle in a one-dimentional box. It is analogous to the fundamental frequency f_1 of a standing wave on a string.

EXAMPLE 39.7 The energy levels of an oil droplet

What is the fundamental quantum of energy for one of Millikan's 1.0-μm-diameter oil droplets confined in a box of length 10 μm? The density of the oil is 900 kg/m^3.

SOLVE The mass of a droplet is $m = \rho V$, where the volume is $\frac{4}{3}\pi r^3$. A quick calculation shows that a 1.0-μm-diameter droplet has mass $m = 4.7 \times 10^{-16}$ kg. The confinement length is $L = 1.0 \times 10^{-5}$ m. From Equation 39.16, the fundamental quantum of energy is

$$E_1 = \frac{h^2}{8mL^2} = \frac{(6.63 \times 10^{-34}\text{ Js})^2}{8(4.7 \times 10^{-16}\text{ kg})(1.0 \times 10^{-5}\text{ m})^2}$$
$$= 1.2 \times 10^{-42}\text{ J} = 7.3 \times 10^{-24}\text{ eV}$$

ASSESS This is such an incredibly small amount of energy that there is no hope of distinguishing between energies of E_1 or $4E_1$ or $9E_1$. For any macroscopic particle, even one this tiny, the allowed energies will *seem* to be perfectly continuous. We will not observe the quantization.

EXAMPLE 39.8 The energy levels of an electron

What are the first three allowed energies for an electron confined in a one-dimensional box of length 0.10 nm, about the size of an atom?

SOLVE We can use Equation 39.16, with $m_{elec} = 9.11 \times 10^{-31}$ kg and $L = 1.0 \times 10^{-10}$ m to find that the fundamental quantum of energy is $E_1 = 6.0 \times 10^{-18}\text{ J} = 38\text{ eV}$. Thus the first three allowed energies of an electron in a 0.10 nm box are

$$E_1 = 38\text{ eV}$$
$$E_2 = 4E_1 = 152\text{ eV}$$
$$E_3 = 9E_1 = 342\text{ eV}$$

We see that confining a wave-like particle creates a standing de Broglie wave, and we know that a standing wave has only certain discrete wavelengths. Thus we find that a confined particle can have only certain discrete energies. In other words, **the confinement of a particle leads directly to the quantization of its energy.** The particle in a box, although not a realistic model of an atom, is a simple example to illustrate

these ideas. An electron confined in a real atom will need to be a much more complex three-dimensional standing wave. But, just like the simple particle in a box, it will have quantized energies. Furthermore, we expect a typical energy difference between adjacent energy levels will be a few electron volts.

Now, this is an intriguing result. We found that visible and ultraviolet photons of light have energies of a few electron volts. We also know that atoms emit *discrete* wavelengths of visible and ultraviolet light, with photon energies of a few electron volts. Now we see that an electron confined in an atomic-size box has energy levels spaced a few electron volts apart. Might there be a connection between these phenomena? We will explore this topic in the next section.

STOP TO THINK 39.3 What is the quantum number of this particle confined in a box?

39.5 Bohr's Model of Atomic Quantization

Activ Online Physics 18.1

Thomson's electron and Rutherford's nucleus made it clear that the atom has a *structure* of some sort. The challenge at the beginning of the 20th century was to deduce, from experimental evidence, the correct structure. The difficulty of this task cannot be exaggerated. The evidence about atoms, such as observations of atomic spectra, was very indirect, and experiments were carried out with only the simplest measuring devices. Using observations as a guide, physicists were attempting to construct a *model* of the atom that could successfully explain the various experiments.

Rutherford's nuclear model was the most successful of various proposals, but Rutherford's model failed to explain why atoms are stable or why their spectra are discrete. A missing piece of the puzzle, although not recognized as such for a few years, was Einstein's 1905 introduction of light quanta. If light comes in discrete packets of energy, which we now call photons, and if atoms emit and absorb light, what does that imply about the structure of the atoms?

This was the question posed by Niels Bohr. Bohr, shown as young man in FIGURE 39.16, was born, educated, and spent most of his life in Denmark. He later established an institute in Copenhagen that, for many decades, was the leading center for the development of quantum physics. Although few discoveries bear Bohr's name, he was the intellectual driving force behind the development of quantum mechanics and the mentor of many of the young physicists who reshaped physics in the 1920s and 1930s.

FIGURE 39.16 Niels Bohr.

After receiving his doctoral degree in physics in 1911, Bohr went to England to work in Rutherford's laboratory. Rutherford had just, within the previous year, completed his development of the nuclear model of the atom. Rutherford's model certainly contained a kernel of truth, but Bohr wanted to understand how a solar-system-like atom could be stable and not radiate away all its energy. He soon recognized that Einstein's light quanta had profound implications for the structure of atoms. In 1913, Bohr proposed a radically new model of the atom in which he added quantization to Rutherford's nuclear atom.

The basic assumptions of the **Bohr model of the atom** are as follows:

1. An atom consists of negative electrons orbiting a very small positive nucleus, as in the Rutherford model.
2. Atoms can exist only in certain **stationary states.** Each stationary state corresponds to a particular set of electron orbits around the nucleus. These states are distinct and can be numbered $n = 1, 2, 3, 4, \ldots$, where n is the *quantum number.*

3. Each stationary state has a discrete, well-defined energy E_n. That is, atomic energies are *quantized.* The stationary states of an atom are numbered in order of increasing energy: $E_1 < E_2 < E_3 < E_4 < \cdots$.
4. The lowest energy state of the atom, with energy E_1, is *stable* and can persist indefinitely. It is called the **ground state** of the atom. Other stationary states with energies $E_2, E_3, E_4, \ldots$ are called **excited states** of the atom.
5. An atom can "jump" from one stationary state to another by emitting or absorbing a photon of frequency

$$f_{\text{photon}} = \frac{\Delta E_{\text{atom}}}{h} \tag{39.17}$$

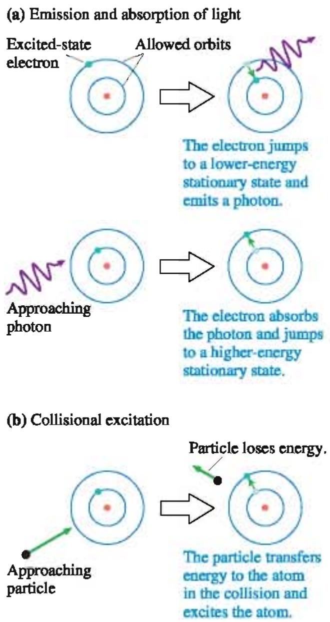

FIGURE 39.17 An atom can change stationary states by emitting or absorbing a photon or by undergoing a collision.

where h is Planck's constant and $\Delta E_{\text{atom}} = |E_f - E_i|$. E_i and E_f are the energies of the initial and final states. Such a jump is called a **transition** or, sometimes, a **quantum jump.** FIGURE 39.17a is a schematic view of the emission and absorption of photons in an atom with stationary states.

6. An atom can move from a lower energy state to a higher energy state by absorbing energy $\Delta E_{\text{atom}} = E_f - E_i$ in an inelastic collision with an electron or another atom. This process, called **collisional excitation,** is shown in FIGURE 39.17b.
7. Atoms seek the lowest energy state. An atom in an excited state, if left alone, will jump to lower and lower energy states until it reaches the ground state.

Bohr's model builds upon Rutherford's model, but it adds two new ideas that are derived from Einstein's ideas of quanta. The first, expressed in assumption 2, is that only certain electron orbits are "allowed" or can exist. The second, expressed in assumption 5, is that **the atom can jump from one state to another by emitting or absorbing a photon of just the right frequency to conserve energy.**

According to Einstein, a photon of frequency f has energy $E_{\text{photon}} = hf$. If an atom jumps from an initial state with energy E_i to a final state with *lower* energy E_f, energy will be conserved if the atom emits a photon with $E_{\text{photon}} = \Delta E_{\text{atom}}$. This photon must have exactly the frequency given by Equation 39.17 if it is to carry away exactly the right amount of energy. Similarly, an atom can jump to a higher energy state, for which additional energy is needed, by absorbing a photon of frequency $f_{\text{photon}} = \Delta E_{\text{atom}}/h$. The total energy of the atom-plus-light system is conserved.

NOTE ▶ When an atom is excited to a higher energy level by absorbing a photon, the photon vanishes. Thus energy conservation requires $E_{\text{photon}} = \Delta E_{\text{atom}}$. When an atom is excited to a higher energy level in a collision with a particle, such as an electron or another atom, the particle still exists after the collision and still has energy. Thus energy conservation requires the less stringent condition $E_{\text{particle}} \geq \Delta E_{\text{atom}}$. ◀

The implications of Bohr's model are profound. In particular:

1. **Matter is stable.** An atom in its ground state has no states of any lower energy to which it can jump. It can remain in the ground state forever.
2. **Atoms emit and absorb a *discrete spectrum*.** Only those photons whose frequencies match the energy *intervals* between the stationary states can be emitted or absorbed. Photons of other frequencies cannot be emitted or absorbed without violating energy conservation.
3. **Emission spectra can be produced by collisions.** In a gas discharge tube, the current-carrying electrons moving through the tube occasionally collide with the atoms. A collision transfers energy to an atom and can kick it to an excited state. Once the atom is in an excited state, it can emit photons of light—a discrete emission spectrum—as it jumps back down to lower-energy states.
4. **Absorption wavelengths are a subset of the wavelengths in the emission spectrum.** Recall that all the lines seen in an absorption spectrum are also seen in emission, but many emission lines are *not* seen in absorption. According to

Bohr's model, most atoms, most of the time, are in their lowest energy state, the $n = 1$ ground state. Thus the absorption spectrum consists of *only* those transitions such as $1 \rightarrow 2$, $1 \rightarrow 3$, ... in which the atom jumps from $n = 1$ to a higher value of n by absorbing a photon. Transitions such as $2 \rightarrow 3$ are *not* observed because there are essentially no atoms in $n = 2$ at any instant of time. On the other hand, atoms that have been excited to the $n = 3$ state by collisions can emit photons corresponding to transitions $3 \rightarrow 1$ *and* $3 \rightarrow 2$. Thus the wavelength corresponding to $\Delta E_{atom} = E_3 - E_1$ is seen in both emission and absorption, but transitions with $\Delta E_{atom} = E_3 - E_2$ occur in emission only.

5. **Each element in the periodic table has a unique spectrum.** The energies of the stationary states are the energies of the orbiting electrons. The atom has no other form of energy. Different elements, with different numbers of electrons, have different stable orbits and thus different stationary states. States with different energies emit and absorb photons of different wavelengths.

EXAMPLE 39.9 The wavelength of an emitted photon

An atom has stationary states with energies $E_j = 4.00$ eV and $E_k = 6.00$ eV. What is the wavelength of a photon emitted in a quantum jump from state k to state j?

MODEL To conserve energy, the emitted photon must have exactly the energy lost by the atom in the quantum jump.

SOLVE The atom can jump from the higher energy state k to the lower energy state j by emitting a photon. The atom's change in energy is $\Delta E_{atom} = -2.00$ eV, so the photon energy must be $E_{photon} = 2.00$ eV. The photon frequency is

$$f = \frac{E_{photon}}{h} = \frac{2.00 \text{ eV}}{4.14 \times 10^{-15} \text{ eV s}} = 4.83 \times 10^{14} \text{ Hz}$$

The wavelength of this photon is

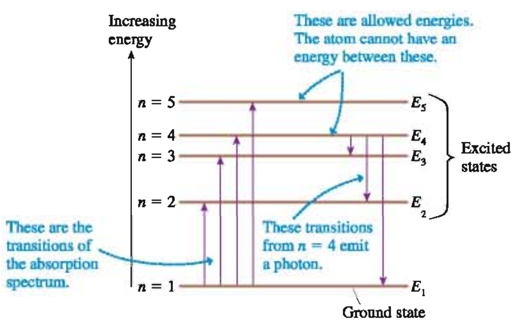
$$\lambda = \frac{c}{f} = 621 \text{ nm}$$

ASSESS 621 nm is a visible-light wavelength.

Energy-Level Diagrams

An **energy-level diagram,** such as the one shown in **FIGURE 39.18**, is a useful pictorial representation of the stationary-state energies. An energy-level diagram is less a graph than it is a picture. The vertical axis represents energy, but the horizontal axis is not a scale. Think of this as a picture of a ladder in which the energies are the rungs of the ladder. The lowest rung, with energy E_1, is the ground state. Higher rungs are labeled by their quantum numbers, $n = 2, 3, 4, \ldots$.

FIGURE 39.18 An energy-level diagram.



Energy-level diagrams are especially useful for showing transitions, or quantum jumps, in which a photon of light is emitted or absorbed. As examples, Figure 39.18 shows upward transitions in which a photon is absorbed by a ground-state atom ($n = 1$) and downward transitions in which a photon is emitted from an $n = 4$ excited state.

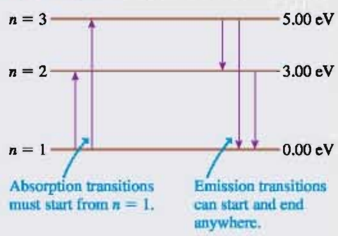
EXAMPLE 39.10 Emission and absorption

An atom has stationary states $E_1 = 0.00$ eV, $E_2 = 3.00$ eV, and $E_3 = 5.00$ eV. What wavelengths are observed in the absorption spectrum and in the emission spectrum of this atom?

MODEL Photons are emitted when an atom undergoes a quantum jump from a higher energy level to a lower energy level. Photons are absorbed in a quantum jump from a lower energy level to a higher energy level. But most of the atoms are in the $n = 1$ ground state, so the only quantum jumps seen in the absorption spectrum start from the $n = 1$ state.

VISUALIZE FIGURE 39.19 shows an energy-level diagram for the atom.

FIGURE 39.19 The atom's energy-level diagram.



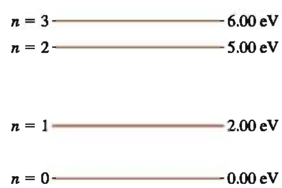
SOLVE This atom will absorb photons on the $1 \to 2$ and $1 \to 3$ transitions, with $\Delta E_{1\to 2} = 3.00$ eV and $\Delta E_{1\to 3} = 5.00$ eV. From $f = \Delta E_{atom}/h$ and $\lambda = c/f$, we find that the wavelengths in the absorption spectrum are

$$1 \to 2 \qquad f = 3.00\text{ eV}/h = 7.25 \times 10^{14}\text{ Hz}$$
$$\lambda = 414\text{ nm (blue)}$$
$$1 \to 3 \qquad f = 5.00\text{ eV}/h = 1.21 \times 10^{15}\text{ Hz}$$
$$\lambda = 248\text{ nm (ultraviolet)}$$

The emission spectrum will also have the 414 nm and 248 nm wavelengths due to the $2 \to 1$ and $3 \to 1$ quantum jumps from excited states 2 and 3 to the ground state. In addition, the emission spectrum will contain the $3 \to 2$ quantum jump with $\Delta E_{3\to 2} = -2.00$ eV that is *not* seen in absorption because there are too few atoms in the $n = 2$ state to absorb. We found in Example 39.9 that a 2.00 eV transition corresponds to a wavelength of 621 nm. Thus the emission wavelengths are

$$2 \to 1 \qquad \lambda = 414\text{ nm (blue)}$$
$$3 \to 1 \qquad \lambda = 248\text{ nm (ultraviolet)}$$
$$3 \to 2 \qquad \lambda = 621\text{ nm (orange)}$$

STOP TO THINK 39.4 A photon with a wavelength of 414 nm has energy $E_{photon} = 3.00$ eV. Do you expect to see a spectral line with $\lambda = 414$ nm in the emission spectrum of the atom represented by this energy-level diagram? If so, what transition or transitions will emit it? Do you expect to see a spectral line with $\lambda = 414$ nm in the absorption spectrum? If so, what transition or transitions will absorb it?



39.6 The Bohr Hydrogen Atom

Bohr's hypothesis was a bold new idea, yet there was still one enormous stumbling block: What *are* the stationary states of an atom? Everything in Bohr's model hinges on the existence of these stationary states, of there being only certain electron orbits that are allowed. But nothing in classical physics provides any basis for such orbits. And Bohr's model describes only the *consequences* of having stationary states, not how to find them. If such states really exist, we will have to go beyond classical physics to find them.

To address this problem, Bohr did an explicit analysis of the hydrogen atom. The hydrogen atom, with only a single electron, was known to be the simplest atom. Furthermore, as we discussed in Chapters 25 and 38, Balmer had discovered a fairly simple formula that characterized the wavelengths in the hydrogen emission spectrum. Anyone with a successful model of an atom was going to have to *derive* Balmer's formula for the hydrogen atom.

Bohr's paper followed a rather circuitous line of reasoning. That is not surprising because he had little to go on at the time. But our goal is a clear explanation of the ideas, not a historical study of Bohr's methods, so we are going to follow a different analysis using de Broglie's matter waves. De Broglie did not propose matter waves until 1924, 11 years after Bohr's paper, but with the clarity of hindsight we can see that treating the electron as a wave provides a more straightforward analysis of the hydrogen atom. Although our route will be different from Bohr's, we will arrive at the same point, and, in addition, we will be in a much better position to understand the work that came after Bohr.

NOTE ▶ Bohr's analysis of the hydrogen atom is sometimes called the *Bohr atom.* It's important not to confuse this analysis, which applies only to hydrogen, with the more general postulates of the *Bohr model of the atom.* Those postulates, which we looked at in Section 39.5, apply to any atom. To make the distinction clear, we'll call Bohr's analysis of hydrogen the *Bohr hydrogen atom.* ◀

The Stationary States of the Hydrogen Atom

FIGURE 39.20 shows a Rutherford hydrogen atom, with a single electron orbiting a nucleus that consists of a single proton. We will assume a circular orbit of radius r and speed v. We will also assume, to keep the analysis manageable, that the proton remains stationary while the electron revolves around it. This is a reasonable assumption because the proton is roughly 1800 times as massive as the electron. With these assumptions, the atom's energy is the kinetic energy of the electron plus the potential energy of the electron-proton interaction. This is

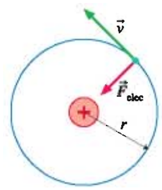


FIGURE 39.20 A Rutherford hydrogen atom. The size of the nucleus is greatly exaggerated.

$$E = K + U = \frac{1}{2}mv^2 + \frac{1}{4\pi\epsilon_0}\frac{q_{\text{elec}}q_{\text{proton}}}{r} = \frac{1}{2}mv^2 - \frac{e^2}{4\pi\epsilon_0 r} \quad (39.18)$$

where we used $q_{\text{elec}} = -e$ and $q_{\text{proton}} = +e$.

NOTE ▶ m is the mass of the electron, *not* the mass of the entire atom. ◀

Now, the electron, as we are coming to understand it, has both particle-like and wave-like properties. First, let us treat the electron as a charged particle. The proton exerts a Coulomb electric force on the electron:

$$\vec{F}_{\text{elec}} = \left(\frac{1}{4\pi\epsilon_0}\frac{e^2}{r^2}, \text{ toward center}\right) \quad (39.19)$$

This force gives the electron an acceleration $\vec{a}_{\text{elec}} = \vec{F}_{\text{elec}}/m$ that also points to the center. This is a centripetal acceleration, causing the particle to move in its circular orbit. The centripetal acceleration of a particle moving in a circle of radius r at speed v *must* be v^2/r, thus

$$a_{\text{elec}} = \frac{F_{\text{elec}}}{m} = \frac{e^2}{4\pi\epsilon_0 mr^2} = \frac{v^2}{r} \quad (39.20)$$

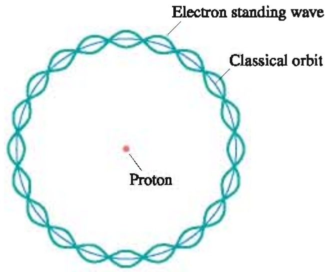
Rearranging, we find

$$v^2 = \frac{e^2}{4\pi\epsilon_0 mr} \quad (39.21)$$

Equation 39.21 is a *constraint* on the motion. The speed v and radius r must obey Equation 39.21 if the electron is to move in a circular orbit. This constraint is not unique to atoms. We earlier found a similar relationship between v and r for orbiting satellites.

Now let's treat the electron as a de Broglie wave. In Section 39.4 we found that a particle confined to a one-dimensional box sets up a standing wave as it reflects back and forth. A standing wave, you will recall, consists of two traveling waves moving in

FIGURE 39.21 An $n = 10$ electron standing wave around the orbit's circumference.



opposite directions. When the round-trip distance in the box is equal to an integer number of wavelengths ($2L = n\lambda$), the two oppositely traveling waves interfere constructively to set up the standing wave.

Suppose that, instead of traveling back and forth along a line, our wave-like particle travels around the circumference of a circle. The particle will set up a standing wave, just like the particle in the box, if there are waves traveling in both directions and if the round-trip distance is an integer number of wavelengths. This is the idea we want to carry over from the particle in a box. As an example, FIGURE 39.21 shows a standing wave around a circle with $n = 10$ wavelengths.

The mathematical condition for a circular standing wave is found by replacing the round-trip distance $2L$ in a box with the round-trip distance $2\pi r$ on a circle. Thus a circular standing wave will occur when

$$2\pi r = n\lambda \qquad n = 1, 2, 3, \ldots \tag{39.22}$$

But the de Broglie wavelength for a particle *has* to be $\lambda = h/p = h/mv$. Thus the standing-wave condition for a de Broglie wave is

$$2\pi r = n\frac{h}{mv}$$

This condition is true only if the electron's speed is

$$v_n = \frac{nh}{2\pi mr} \qquad n = 1, 2, 3, \ldots \tag{39.23}$$

The quantity $h/2\pi$ occurs so often in quantum physics that it is customary to give it a special name. We define the quantity $\hbar$, pronounced "h bar," as

$$\hbar \equiv \frac{h}{2\pi} = 1.055 \times 10^{-34}\,\mathrm{J\,s} = 6.58 \times 10^{-16}\,\mathrm{eV\,s}$$

With this definition, we can write Equation 39.23 as

$$v_n = \frac{n\hbar}{mr} \qquad n = 1, 2, 3, \ldots \tag{39.24}$$

This, like Equation 39.21, is another relationship between v and r. This is the constraint that arises from treating the electron as a wave.

Now if the electron can act as both a particle *and* a wave, then both the Equation 39.21 *and* Equation 39.24 constraints have to be obeyed. That is, v^2 as given by the Equation 39.21 particle constraint has to equal v^2 of the Equation 39.24 wave constraint. Equating these gives

$$v^2 = \frac{e^2}{4\pi\epsilon_0 mr} = \frac{n^2\hbar^2}{m^2r^2}$$

We can solve this equation to find that the radius r is

$$r_n = n^2\frac{4\pi\epsilon_0\hbar^2}{me^2} \qquad n = 1, 2, 3, \ldots \tag{39.25}$$

where we have added a subscript n to the radius r to indicate that it depends on the integer n.

The right-hand side of Equation 39.25, except for the n^2, is just a collection of constants. Let's group them all together and define the **Bohr radius** a_B as

$$a_B = \text{Bohr radius} \equiv \frac{4\pi\epsilon_0\hbar^2}{me^2} = 5.29 \times 10^{-11}\,\mathrm{m} = 0.0529\,\mathrm{nm}$$

With this definition, Equation 39.25 for the radius of the electron's orbit becomes

$$r_n = n^2 a_B \qquad n = 1, 2, 3, \ldots \tag{39.26}$$

The first few allowed values of r_n are

$$r_n = \begin{cases} 0.053 \text{ nm} & n = 1 \\ 0.212 \text{ nm} & n = 2 \\ 0.476 \text{ nm} & n = 3 \\ \vdots & \vdots \end{cases}$$

We have discovered stationary states! That is, **a hydrogen atom can exist *only* if the radius of the electron's orbit is one of the values given by Equation 39.26.** Intermediate values of the radius, such as $r = 0.100$ nm, cannot exist because the electron cannot set up a standing wave around the circumference. The possible orbits are *quantized,* with only certain orbits allowed.

The key step leading to Equation 39.26 was the requirement that the electron have wave-like properties in addition to particle-like properties. This requirement leads to quantized orbits, or what Bohr called stationary states. The integer n is thus the *quantum number* that numbers the various stationary states.

Hydrogen Atom Energy Levels

Now we can make progress quickly. Knowing the possible radii, we can return to Equation 39.23 and find the possible electron speeds to be

$$v_n = \frac{n\hbar}{mr_n} = \frac{1}{n}\frac{\hbar}{ma_B} = \frac{v_1}{n} \qquad n = 1, 2, 3, \ldots \tag{39.27}$$

where $v_1 = \hbar/ma_B = 2.19 \times 10^6$ m/s is the electron's speed in the $n = 1$ orbit. The speed decreases as n increases.

Finally, we can determine the energies of the stationary states. From Equation 39.18 for the energy, with Equations 39.26 and 39.27 for r and v, we have

$$E_n = \frac{1}{2}mv_n^2 - \frac{e^2}{4\pi\epsilon_0 r_n} = \frac{1}{2}m\left(\frac{\hbar^2}{m^2 a_B^{\,2} n^2}\right) - \frac{e^2}{4\pi\epsilon_0 n^2 a_B} \tag{39.28}$$

As a homework problem, you can show that this rather messy expression simplifies to

$$E_n = -\frac{1}{n^2}\left(\frac{1}{4\pi\epsilon_0}\frac{e^2}{2a_B}\right) \tag{39.29}$$

Let's define

$$E_1 \equiv \frac{1}{4\pi\epsilon_0}\frac{e^2}{2a_B} = 13.60 \text{ eV}$$

We can then write the energy levels of the stationary states of the hydrogen atom as

$$E_n = -\frac{E_1}{n^2} = -\frac{13.60 \text{ eV}}{n^2} \qquad n = 1, 2, 3, \ldots \tag{39.30}$$

This has been a lot of math, so we need to see where we are and what we have learned. Table 39.2 on the next page shows values of r_n, v_n, and E_n evaluated for quantum number values $n = 1$ to 5. We do indeed seem to have discovered stationary states of the hydrogen atom. Each state, characterized by its quantum number n, has a unique radius, speed, and energy. These are displayed graphically in FIGURE 39.22, on the next page, in which the orbits are drawn to scale. Notice how the atom's diameter increases very rapidly as n increases. At the same time, the electron's speed decreases.

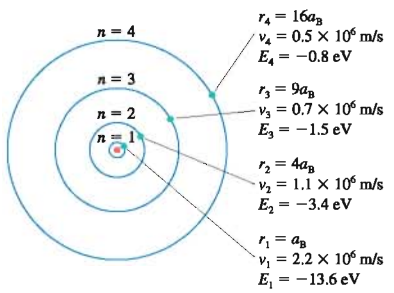


FIGURE 39.22 The first four stationary states, or allowed orbits, of the Bohr hydrogen atom drawn to scale.

TABLE 39.2 Radii, speeds, and energies for the first five states of the Bohr hydrogen atom

n	r_n (nm)	v_n (m/s)	E_n (eV)
1	0.053	2.19×10^6	−13.60
2	0.212	1.09×10^6	−3.40
3	0.476	0.73×10^6	−1.51
4	0.846	0.55×10^6	−0.85
5	1.322	0.44×10^6	−0.54

EXAMPLE 39.11 Stationary states of the hydrogen atom

Can an electron in a hydrogen atom have a speed of 3.60×10^5 m/s? If so, what are its energy and the radius of its orbit? What about a speed of 3.65×10^5 m/s?

SOLVE To be in a stationary state, the electron must have speed

$$v_n = \frac{v_1}{n} = \frac{2.19 \times 10^6 \text{ m/s}}{n}$$

where n is an integer. A speed of 3.60×10^5 m/s would require quantum number

$$n = \frac{2.19 \times 10^6 \text{ m/s}}{3.60 \times 10^5 \text{ m/s}} = 6.08$$

This is not an integer, so the electron can *not* have this speed. But if $v = 3.65 \times 10^5$ m/s, then

$$n = \frac{2.19 \times 10^6 \text{ m/s}}{3.65 \times 10^5 \text{ m/s}} = 6$$

This is the speed of an electron in the $n = 6$ excited state. An electron in this state has energy

$$E_6 = -\frac{13.60 \text{ eV}}{6^2} = -0.38 \text{ eV}$$

and the radius of its orbit is

$$r_6 = 6^2(5.29 \times 10^{-11} \text{ nm}) = 1.90 \times 10^{-9} \text{ m} = 1.90 \text{ nm}$$

Binding Energy and Ionization Energy

It is important to understand why the energies of the stationary states are negative. Because the potential energy of two charged particles is $U = q_1q_2/4\pi\epsilon_0 r$, the zero of potential energy occurs at $r = \infty$ where the particles are infinitely far apart. The state of zero total energy corresponds to having the electron at rest ($K = 0$) and infinitely far from the proton ($U = 0$). This situation, which is the case of two "free particles," occurs in the limit $n \to \infty$, for which $r_n \to \infty$ and $v_n \to 0$.

An electron and a proton bound into an atom have *less* energy than two free particles. We know this because we would have to do work (i.e., add energy) to pull the electron and proton apart. If the bound atom has less energy than two free particles, and if the total energy of two free particles is zero, then it must be the case that the atom has a *negative* amount of energy.

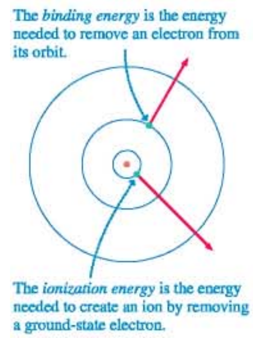
Thus $|E_n|$ is the **binding energy** of the electron in stationary state n. In the ground state, where $E_1 = -13.60$ eV, we would have to add 13.60 eV to the electron to free it from the proton and reach the zero energy state of two free particles. We can say that the electron in the ground state is "bound by 13.60 eV." An electron in an $n = 3$ orbit, where it is farther from the proton and moving more slowly, is bound by only 1.51 eV. That is the amount of energy you would have to supply to remove the electron from an $n = 3$ orbit.

Removing the electron entirely leaves behind a positive ion, H^+ in the case of a hydrogen atom. (The fact that H^+ happens to be a proton does not alter the fact that it is also an atomic ion.) Because nearly all atoms are in their ground state, the binding energy $|E_1|$ of the ground state is called the **ionization energy** of an atom. Bohr's

analysis predicts that the ionization energy of hydrogen is 13.60 eV. FIGURE 39.23 illustrates the ideas of binding energy and ionization energy.

We can test this prediction by shooting a beam of electrons at hydrogen atoms. A projectile electron can knock out an atomic electron if its kinetic energy K is greater than the atom's ionization energy, leaving an ion behind. But a projectile electron will be unable to cause ionization if its kinetic energy is less than the atom's ionization energy. This is a fairly straightforward experiment to carry out, and the evidence shows that the ionization energy of hydrogen is, indeed, 13.60 eV.

FIGURE 39.23 Binding energy and ionization energy.



Quantization of Angular Momentum

The angular momentum of a particle in circular motion, whether it is a planet or an electron, is

$$L = mvr$$

You will recall that angular momentum is conserved in orbital motion because a force directed toward a central point exerts no torque on the particle. Bohr used conservation of energy explicitly in his analysis of the hydrogen atom, but what role does conservation of angular momentum play?

The condition that a de Broglie wave for the electron set up a standing wave around the circumference was given, in Equation 39.22, as

$$2\pi r = n\lambda = n\frac{h}{mv}$$

We can rewrite this equation as

$$mvr = n\frac{h}{2\pi} = n\hbar \tag{39.31}$$

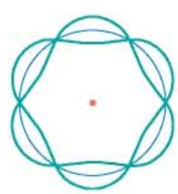
But mvr is the angular momentum L for a particle in a circular orbit. It appears that the angular momentum of an orbiting electron cannot have just any value. Instead, it must satisfy

$$\boxed{L = n\hbar \qquad n = 1, 2, 3, \ldots} \tag{39.32}$$

Thus angular momentum also is quantized! The electron's angular momentum must be an integer multiple of Planck's constant $\hbar$.

The quantization of angular momentum is a direct consequence of this wave-like nature of the electron. We will find that the quantization of angular momentum plays a major role in the behavior of more complex atoms, leading to the idea of electron shells that you likely have studied in chemistry.

STOP TO THINK 39.5 What is the quantum number of this hydrogen atom?



39.7 The Hydrogen Spectrum

Our analysis of the hydrogen atom has revealed stationary states, but how do we know whether the results make any sense? The most important experimental evidence that we have about the hydrogen atom is its spectrum, so the primary test of the Bohr hydrogen atom is whether it correctly predicts the spectrum.

The Hydrogen Energy-Level Diagram

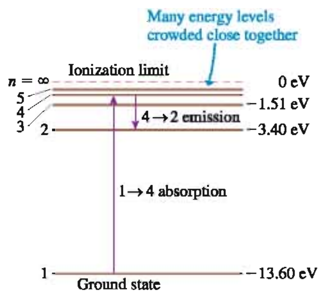


FIGURE 39.24 The energy-level diagram of the hydrogen atom.

FIGURE 39.24 is an energy-level diagram for the hydrogen atom. As we noted earlier, the energies are like the rungs of a ladder. The lowest rung is the ground state, with $E_1 = -13.60$ eV. The top rung, with $E = 0$ eV, corresponds to a hydrogen ion in the limit $n \to \infty$. This top rung is called the **ionization limit.** In principle there are an infinite number of rungs, but only the lowest few are shown. The higher values of n are all crowded together just below the ionization limit at $n = \infty$.

The figure shows a $1 \to 4$ transition in which a photon is absorbed and a $4 \to 2$ transition in which a photon is emitted. For two quantum states m and n, where $n > m$ and E_n is the higher energy state, an atom can *emit* a photon in an $n \to m$ transition or *absorb* a photon in an $m \to n$ transition.

The Emission Spectrum

According to the fifth assumption of Bohr's model of atomic quantization, the frequency of the photon emitted in an $n \to m$ transition is

$$f = \frac{\Delta E_{\text{atom}}}{h} = \frac{E_n - E_m}{h} \tag{39.33}$$

We can use Equation 39.29 for the energies E_n and E_m to predict that the emitted photon has frequency

$$\begin{aligned} f &= \frac{1}{h}\left\{\left[-\frac{1}{n^2}\left(\frac{1}{4\pi\epsilon_0}\frac{e^2}{2a_B}\right)\right] - \left[-\frac{1}{m^2}\left(\frac{1}{4\pi\epsilon_0}\frac{e^2}{2a_B}\right)\right]\right\} \\ &= \frac{1}{4\pi\epsilon_0}\frac{e^2}{2ha_B}\left(\frac{1}{m^2} - \frac{1}{n^2}\right) \end{aligned} \tag{39.34}$$

The frequency is a positive number because $m < n$ and thus $1/m^2 > 1/n^2$.

We are more interested in wavelength than frequency, because wavelengths are the quantity measured by experiment. The wavelength of the photon emitted in an $n \to m$ quantum jump is

$$\lambda_{n \to m} = \frac{c}{f} = \frac{8\pi\epsilon_0 hca_B/e^2}{\left(\dfrac{1}{m^2} - \dfrac{1}{n^2}\right)} \tag{39.35}$$

This looks rather gruesome, but notice that the numerator is simply a collection of various constants. The value of the numerator, which we can call λ_0, is

$$\lambda_0 = \frac{8\pi\epsilon_0 hca_B}{e^2} = 9.112 \times 10^{-8}\text{ m} = 91.12\text{ nm}$$

With this definition, our prediction for the wavelengths in the hydrogen emission spectrum is

$$\lambda_{n \to m} = \frac{\lambda_0}{\left(\dfrac{1}{m^2} - \dfrac{1}{n^2}\right)} \qquad m = 1, 2, 3, \ldots \qquad n = m + 1, m + 2, \ldots \tag{39.36}$$

This should look familiar. It is the Balmer formula from Chapter 38! However, there is one *slight* difference: Bohr's analysis of the hydrogen atom has predicted

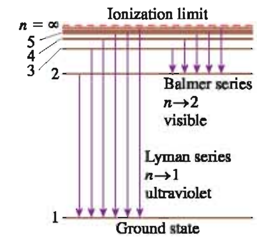
$\lambda_0 = 91.12$ nm, whereas Balmer found, from experiment, that $\lambda_0 = 91.18$ nm. Could Bohr have come this close but then fail to predict the Balmer formula correctly?

The problem, it turns out, is in our assumption that the proton remains at rest while the electron orbits it. In fact, *both* particles rotate about their common center of mass, rather like a dumbbell with a big end and a small end. The center of mass is very close to the proton, which is far more massive than the electron, but the proton is not entirely motionless. The good news is that a more advanced analysis can account for the proton's motion. It changes the energies of the stationary states ever so slightly—about 1 part in 2000—but that is precisely what is needed to give a revised value:

$$\lambda_0 = 91.18 \text{ nm when corrected for the nuclear motion}$$

It works! Unlike all previous atomic models, **the Bohr hydrogen atom correctly predicts the discrete spectrum of the hydrogen atom.** FIGURE 39.25 shows the *Balmer series* and the *Lyman series* transitions on an energy-level diagram. Only the Balmer series, consisting of transitions ending on the $m = 2$ state, gives visible wavelengths, and this is the series that Balmer initially analyzed. The Lyman series, ending on the $m = 1$ ground state, is in the ultraviolet region of the spectrum and was not measured until later. These series, as well as others in the infrared, are observed in a discharge tube where collisions with electrons excite the atoms upward from the ground state to state n. They then decay downward by emitting photons. Only the Lyman series is observed in the absorption spectrum because, as noted previously, essentially all the atoms in a quiescent gas are in the ground state.

FIGURE 39.25 Transitions producing the Lyman series and the Balmer series of lines in the hydrogen spectrum.



EXAMPLE 39.12 Hydrogen absorption

Whenever astronomers look at distant galaxies, they find that the light has been strongly absorbed at the wavelength of the $1 \rightarrow 2$ transition in the Lyman series of hydrogen. This absorption tells us that interstellar space is filled with vast clouds of hydrogen left over from the Big Bang. What is the wavelength of the $1 \rightarrow 2$ absorption in hydrogen?

SOLVE Equation 39.36 predicts the *absorption* spectrum of hydrogen if we let $m = 1$. The absorption seen by astronomers is from the ground state of hydrogen ($m = 1$) to its first excited state ($n = 2$). The wavelength is

$$\lambda_{1\rightarrow 2} = \frac{91.18 \text{ nm}}{\left(\frac{1}{1^2} - \frac{1}{2^2}\right)} = 121.6 \text{ nm}$$

ASSESS This wavelength is far into the ultraviolet. Ground-based astronomy cannot observe this region of the spectrum because the wavelengths are strongly absorbed by the atmosphere, but with space-based telescopes, first widely used in the 1970s, astronomers see 121.6 nm absorption in nearly every direction they look.

Hydrogen-Like Ions

An ion with a *single* electron orbiting Z protons in the nucleus is called a **hydrogen-like ion.** Z is the atomic number and describes the number of protons in the nucleus. He^+, with one electron circling a $Z = 2$ nucleus, and Li^{++}, with one electron and a $Z = 3$ nucleus, are hydrogen-like ions. So is U^{+91}, with one lonely electron orbiting a $Z = 92$ uranium nucleus.

Any hydrogen-like ion is simply a variation on the Bohr hydrogen atom. The only difference between a hydrogen-like ion and neutral hydrogen is that the potential energy $-e^2/4\pi\epsilon_0 r$ becomes, instead, $-Ze^2/4\pi\epsilon_0 r$. Hydrogen itself is the $Z = 1$ case. If we repeat the analysis of the previous sections with this one change, we find:

$$\begin{aligned} r_n &= \frac{n^2 a_B}{Z} \\ v_n &= Z\frac{v_1}{n} \\ E_n &= -\frac{13.60Z^2 \text{ eV}}{n^2} \\ \lambda_0 &= \frac{91.18 \text{ nm}}{Z^2} \end{aligned} \tag{39.37}$$

As the nuclear charge increases, the electron moves into a smaller-diameter, higher-speed orbit. Its ionization energy $|E_1|$ increases significantly, and its spectrum shifts to shorter wavelengths. Table 39.3 compares the ground-state atomic diameter $2r_1$, the ionization energy $|E_1|$, and the first wavelength $3 \rightarrow 2$ in the Balmer series for hydrogen and the first two hydrogen-like ions.

TABLE 39.3 Comparison of hydrogen-like ions with $Z = 1$, 2, and 3

Ion	Diameter $2r_1$	Ionization energy $\lvert E_1 \rvert$	Wavelength of $3 \rightarrow 2$
H ($Z = 1$)	0.106 nm	13.6 eV	656 nm
He^+ ($Z = 2$)	0.053 nm	54.4 eV	164 nm
Li^{++} ($Z = 3$)	0.035 nm	125.1 eV	73 nm

Success and Failure

Bohr's analysis of the hydrogen atom seemed to be a resounding success. By introducing Einstein's ideas about light quanta, Bohr was able to provide the first understanding of discrete spectra and to predict the Balmer formula for the wavelengths in the hydrogen spectrum. And the Bohr hydrogen atom, unlike Rutherford's model, was stable. There was clearly some validity to the idea of stationary states.

But Bohr was completely unsuccessful at explaining the spectra of any other neutral atom. His method did not work even for helium, the second element in the periodic table with a mere two electrons. Something inherent in Bohr's assumptions seemed to work correctly for a single electron but not in situations with two or more electrons.

It is important to make a distinction between the Bohr model of atomic quantization, described in Section 39.5, and the Bohr hydrogen atom. The Bohr model assumes that stationary states exist, but it does not say how to find them. We found the stationary states of a hydrogen atom by requiring that an integer number of de Broglie waves fit around the circumference of the orbit, setting up standing waves. The difficulty with more complex atoms is not the Bohr model but the method of finding the stationary states. Bohr's model of the atomic quantization remains valid, and we will continue to use it, but the procedure of fitting standing waves to a circle is just too simple to find the stationary states of complex atoms. We need to find a better procedure.

Einstein, de Broglie, and Bohr carried physics into uncharted waters. Their successes made it clear that the microscopic realm of light and atoms is governed by quantization, discreteness, and a blurring of the distinction between particles and waves. Although Bohr was clearly on the right track, his inability to extend the Bohr hydrogen atom to more complex atoms made it equally clear that the complete and correct theory remained to be discovered. Bohr's theory was what we now call "semiclassical," a hybrid of classical Newtonian mechanics with the new ideas of quanta. Still missing was a complete theory of motion and dynamics in a quantized universe—a *quantum* mechanics.

SUMMARY

The goal of Chapter 39 has been to understand the quantization of energy for light and matter.

General Principles

Light has particle-like properties

- The energy of a light wave comes in discrete packets called light quanta or **photons**.
- For light of frequency f, the energy of each photon is $E = hf$, where h is **Planck's constant.**
- For a light wave that delivers power P, photons arrive at rate R such that $P = Rhf$.
- Photons are "particle-like" but are not classical particles.

Matter has wave-like properties

- The **de Broglie wavelength** of a "particle" of mass m is $\lambda = h/mv$.
- The wave-like nature of matter is seen in the interference patterns of electrons, neutrons, and entire atoms.
- When a particle is confined, it sets up a de Broglie standing wave. The fact that standing waves have only certain allowed wavelengths leads to the conclusion that a confined particle has only certain allowed energies. That is, energy is quantized.

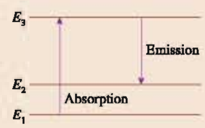
Important Concepts

Einstein's Model of Light

- Light consists of quanta of energy $E = hf$.
- Quanta are emitted and absorbed on an all-or-nothing basis.
- When a light quantum is absorbed, it delivers all its energy to *one* electron.

Bohr's Model of the Atom

- An atom can exist in only certain stationary states. The allowed energies are quantized. State n has energy E_n.
- An atom can jump from one stationary state to another by emitting or absorbing a photon with $E_{photon} = hf = \Delta E_{atom}$.
- Atoms can be excited in inelastic collisions.
- Atoms seek the $n = 1$ **ground state.** Most atoms, most of the time, are in the ground state.



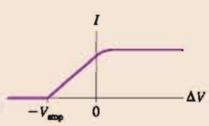
Applications

Photoelectric effect

Light can eject electrons from a metal only if $f \geq f_0 = E_0/h$, where E_0 is the metal's **work function.**

The **stopping potential** that stops even the fastest electrons is

$$V_{stop} = \frac{h}{e}(f - f_0)$$



Particle in a box

A particle confined to a one-dimensional box of length L sets up de Broglie standing waves. The allowed energies are

$$E_n = \frac{1}{2}mv_n^2 = n^2\frac{h^2}{8mL^2} \qquad n = 1, 2, 3, \ldots$$

The Bohr hydrogen atom

The stationary states are found by requiring an integer number of de Broglie wavelengths to fit around the circumference of the electron's orbit: $2\pi r = n\lambda$.

This leads to energy quantization with

$$r_n = n^2 a_B \qquad v_n = \frac{v_1}{n} \qquad E_n = -\frac{13.60\,\text{eV}}{n^2}$$

where $a_B = 0.0529$ nm is the **Bohr radius.** The Bohr hydrogen atom successfully predicts the Balmer formula for the hydrogen spectrum. Angular momentum is also quantized, with $L = n\hbar$.

Terms and Notation

photoelectric effect	wave packet	Bohr model of the atom	Bohr radius, a_B
threshold frequency, f_0	matter wave	stationary state	binding energy
stopping potential, V_{stop}	de Broglie wavelength	ground state	ionization energy, $\lvert E_1 \rvert$
thermal emission	quantized	excited state	ionization limit
work function, E_0	energy level	transition	hydrogen-like ion
Planck's constant, h or $\hbar$	quantum number, n	quantum jump	
light quantum	fundamental quantum of energy, E_1	collisional excitation	
photon		energy-level diagram

Problems labeled integrate significant material from earlier chapters.

CONCEPTUAL QUESTIONS

1. a. A negatively charged electroscope can be discharged by shining an ultraviolet light on it. How does this happen?
   b. You might think that an ultraviolet light shining on an initially uncharged electroscope would cause the electroscope to become positively charged as photoelectrons are emitted. In fact, ultraviolet light has no noticeable effect on an uncharged electroscope. Why not?
2. a. Explain why the graphs of Figure 39.3 are horizontal for $\Delta V > 0$.
   b. Explain why photoelectrons are ejected from the cathode with a range of kinetic energies, rather than all electrons having the same kinetic energy.
   c. Explain the reasoning by which we claim that the stopping potential V_{stop} indicates the maximum kinetic energy of the electrons.
3. How would the graph of Figure 39.2 look *if* classical physics provided the correct description of the photoelectric effect? Draw the graph and explain your reasoning. Assume that the light intensity remains constant as its frequency and wavelength are varied.
4. How would the graphs of Figure 39.3 look *if* classical physics provided the correct description of the photoelectric effect? Draw the graph and explain your reasoning. Include curves for both weak light and intense light.
5. FIGURE Q39.5 is the current-versus-potential-difference graph for a photoelectric-effect experiment with an unknown metal. *If* classical physics provided the correct description of the photoelectric effect, how would the graph look if:
   a. The light was replaced by an equally intense light with a shorter wavelength? Draw it.
   b. The metal was replaced by a different metal with a smaller work function? Draw it.

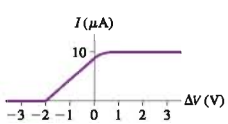

FIGURE Q39.5

6. Metal 1 has a larger work function than metal 2. Both are illuminated with the same short-wavelength ultraviolet light. Do photoelectrons from metal 1 have a higher speed, a lower speed, or the same speed as photoelectrons from metal 2? Explain.
7. Electron 1 is accelerated from rest through a potential difference of 100 V. Electron 2 is accelerated from rest through a potential difference of 200 V. Afterward, which electron has the larger de Broglie wavelength? Explain.
8. An electron and a proton are each accelerated from rest through a potential difference of 100 V. Afterward, which particle has the larger de Broglie wavelength? Explain.
9. Imagine that the horizontal box of Figure 39.15 is instead oriented vertically. Also imagine the box to be on a neutron star where the gravitational field is so strong that the particle in the box slows significantly, nearly stopping, before it hits the top of the box. Make a *qualitative* sketch of the $n = 3$ de Broglie standing wave of a particle in this box.
   Hint: The nodes are *not* uniformly spaced.
10. If an electron is in a *stationary state* of an atom, is the electron at rest? If not, what does the term mean?
11. FIGURE Q39.11 shows the energy-level diagram of Element X.
    a. What is the ionization energy of Element X?
    b. An atom in the ground state absorbs a photon, then emits a photon with a wavelength of 1240 nm. What conclusion can you draw about the energy of the photon that was absorbed?
    c. An atom in the ground state has a collision with an electron, then emits a photon with a wavelength of 1240 nm. What conclusion can you draw about the initial kinetic energy of the electron?

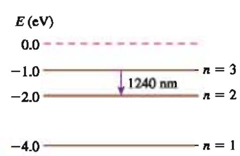

FIGURE Q39.11

EXERCISES AND PROBLEMS

Exercises

Section 39.1 The Photoelectric Effect

Section 39.2 Einstein's Explanation

1. | How many photoelectrons are ejected per second in the experiment represented by the graph of FIGURE EX39.1?

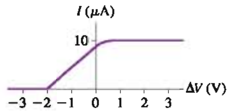

FIGURE EX39.1

2. | Which metals in Table 39.1 exhibit the photoelectric effect for (a) light with $\lambda = 400$ nm and (b) light with $\lambda = 250$ nm?
3. | Photoelectrons are observed when a metal is illuminated by light with a wavelength less than 388 nm. What is the metal's work function?
4. || Electrons in a photoelectric-effect experiment emerge from a tungsten surface with a maximum kinetic energy of 1.30 eV. What is the wavelength of the light?
5. | You need to design a photodetector that can respond to the entire range of visible light. What is the maximum possible work function of the cathode?
6. | Use Millikan's photoelectric-effect data in Figure 39.10 to determine:
   a. The work function, in eV, of cesium.
   b. An experimental value of Planck's constant.
7. | A photoelectric-effect experiment finds a stopping potential of 1.93 V when light of 200 nm is used to illuminate the cathode.
   a. From what metal is the cathode made?
   b. What is the stopping potential if the intensity of the light is doubled?

Section 39.3 Photons

8. | a. Determine the energy, in eV, of a photon with a 700 nm wavelength.
   b. Determine the wavelength of a 5.0 keV x-ray photon.
9. | What is the wavelength, in nm, of a photon with energy (a) 0.30 eV, (b) 3.0 eV, and (c) 30 eV? For each, is this wavelength visible, ultraviolet, or infrared light?
10. | What is the energy, in eV, of (a) a 100 MHz radio-frequency photon, (b) a visible-light photon with a wavelength of 500 nm, and (c) an x-ray photon with a wavelength of 0.10 nm?
11. | An FM radio station broadcasts with a power of 10 kW at a frequency of 101 MHz.
   a. How many photons does the antenna emit each second?
   b. Should the broadcast be treated as an electromagnetic wave or discrete photons? Explain.
12. | A red laser with a wavelength of 650 nm and a blue laser with a wavelength of 450 nm emit laser beams with the same light power. How do their rates of photon emission compare? Answer this by computing R_{red}/R_{blue}.
13. | A 100 W lightbulb emits about 5 W of visible light. (The other 95 W are emitted as infrared radiation or lost as heat to the surroundings.) The average wavelength of the visible light is about 600 nm, so make the simplifying assumption that all the light has this wavelength.
   a. What is the frequency of the emitted light?
   b. How many visible-light photons does the bulb emit per second?

Section 39.4 Matter Waves and Energy Quantization

14. || At what speed is an electron's de Broglie wavelength (a) 1.0 pm, (b) 1.0 nm, (c) 1.0 μm, and (d) 1.0 mm?
15 || Through what potential difference must an electron be accelerated from rest to have a de Broglie wavelength of 500 nm?
16. || The diameter of the nucleus is about 10 fm. What is the kinetic energy, in MeV, of a proton with a de Broglie wavelength of 10 fm?
17. | What is the quantum number of an electron confined in a 3.0-nm-long one-dimentional box if the electron's de Broglie wavelength is 1.0 nm?
18. | The diameter of the nucleus is about 10 fm. A simple model of the nucleus is that protons and neutrons are confined within a one-dimensional box of length 10 fm. What are the first three energy levels, in MeV, for a proton in such a box?
19. || What is the length of a one-dimensional box in which an electron in the $n = 1$ state has the same energy as a photon with a wavelength of 600 nm?

Section 39.5 Bohr's Model of Atomic Quantization

20. | FIGURE EX39.20 is an energy-level diagram for a simple atom. What wavelengths appear in the atom's (a) emission spectrum and (b) absorption spectrum?

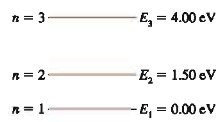

FIGURE EX39.20

21. || An electron with 2.00 eV of kinetic energy collides with the atom shown in FIGURE EX39.20.
   a. Is the electron able to kick the atom to an excited state? Why or why not?
   b. If your answer to part a was yes, what is the electron's kinetic energy after the collision?
22. || The allowed energies of a simple atom are 0.00 eV, 4.00 eV, and 6.00 eV.
   a. Draw the atom's energy-level diagram. Label each level with the energy and the quantum number.
   b. What wavelengths appear in the atom's emission spectrum?
   c. What wavelengths appear in the atom's absorption spectrum?

23. || The allowed energies of a simple atom are 0.00 eV, 4.00 eV, and 6.00 eV. An electron traveling with a speed of 1.30×10^6 m/s collides with the atom. Can the electron excite the atom to the $n = 2$ stationary state? The $n = 3$ stationary state? Explain.

Section 39.6 The Bohr Hydrogen Atom

24. | Show, by actual calculation, that the Bohr radius is 0.0529 nm and that the ground-state energy of hydrogen is -13.60 eV.
25. || a. What quantum number of the hydrogen atom comes closest to giving a 100-nm-diameter electron orbit?
    b. What are the electron's speed and energy in this state?
26. || a. Calculate the de Broglie wavelength of the electron in the $n = 1$, 2, and 3 states of the hydrogen atom. Use the information in Table 39.2.
    b. Show numerically that the circumference of the orbit for each of these stationary states is exactly equal to n de Broglie wavelengths.
    c. Sketch the de Broglie standing wave for the $n = 3$ orbit.
27. | How much energy does it take to ionize a hydrogen atom that is in its first excited state?
28. | Show, by calculation, that the first three states of the hydrogen atom have angular momenta $\hbar$, $2\hbar$, and $3\hbar$, respectively.
29. | Show that Planck's constant $\hbar$ has units of angular momentum.

Section 39.7 The Hydrogen Spectrum

30. | Determine the wavelengths of all the possible photons that can be emitted from the $n = 4$ state of a hydrogen atom.
31. | What is the third-longest wavelength in the absorption spectrum of hydrogen?
32. | Is a spectral line with wavelength 656.5 nm seen in the absorption spectrum of hydrogen atoms? Why or why not?
33. || Find the radius of the electron's orbit, the electron's speed, and the energy of the atom for the first three stationary states of He^+.

Problems

34. || For what wavelength of light does a 100 mW laser deliver 2.50×10^{17} photons per second?
35. || A ruby laser emits an intense pulse of light that lasts a mere 10 ns. The light has a wavelength of 690 nm, and each pulse has an energy of 500 mJ.
    a. How many photons are emitted in each pulse?
    b. What is the *rate* of photon emission, in photons per second, during the 10 ns that the laser is "on"?
36. || In a photoelectric-effect experiment, the wavelength of light shining on an aluminum cathode is decreased from 250 nm to 200 nm. What is the change in the stopping potential?
37. || Potassium and gold cathodes are used in a photoelectric-effect experiment. For each cathode, find:
    a. The threshold frequency.
    b. The threshold wavelength.
    c. The maximum photoelectron ejection speed if the light has a wavelength of 220 nm.
    d. The stopping potential if the wavelength is 220 nm.
38. ||| The maximum kinetic energy of photoelectrons is 2.8 eV. When the wavelength of the light is increased by 50%, the maximum energy decreases to 1.1 eV. What are (a) the work function of the cathode and (b) the initial wavelength of the light?
39. || In a photoelectric-effect experiment, the stopping potential at a wavelength of 400 nm is 25.7% of the stopping potential at a wavelength of 300 nm. Of what metal is the cathode made?
40. || The graph in FIGURE P39.40 was measured in a photoelectric-effect experiment.
    a. What is the work function (in eV) of the cathode?
    b. What experimental value of Planck's constant is obtained from these data?

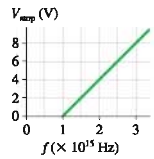

FIGURE P39.40

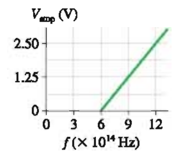

FIGURE P39.41

41. || FIGURE P39.41 shows the stopping potential versus the light frequency for a metal cathode used in a photoelectric-effect experiment. Suppose this cathode is now illuminated with 10 μW of 300 nm light and that the efficiency of converting photons to photoelectrons is 10%.
    a. What is the current I when the anode is positive?
    b. Draw a graph showing current I versus potential difference ΔV for potential difference values from -3 V to $+3$ V. Include a numerical scale on both axes.
42. || In a photoelectric-effect experiment, the stopping potential was measured for several different wavelengths of incident light. The data are shown in the table. Analyze these data to determine:
    a. The metal used for the cathode.
    b. An experimental value for Planck's constant. Your value should be found using *all* the data.

λ (nm)	V_{stop} (volts)
500	0.19
450	0.48
400	0.83
350	1.28
300	1.89
250	2.74

43. || The relationship between momentum and energy from Einstein's theory of relativity is $E^2 - (pc)^2 = E_0^2$, where, in this context, $E_0 = mc^2$ is the rest energy rather than the work function.
    a. A photon is a massless particle. What is a photon's momentum p in terms of its energy E?
    b. Einstein also claimed that the energy of a photon is related to its frequency by $E = hf$. Use this and your result from part a to write an expression for the wavelength λ of a photon in terms of its momentum p.
    c. Your result for part b is for a "particle-like wave." Suppose you thought this expression should also apply to a "wave-like particle." What is your expression for λ if you replace p with the classical-mechanics expression for the momentum of a particle of mass m? Is this a familiar-looking expression?

44. The electron interference pattern of Figure 39.13 was made by shooting electrons with 50 keV of kinetic energy through two slits spaced 1.0 μm apart. The fringes were recorded on a detector 1.0 m behind the slits.
   a. What was the speed of the electrons? (The speed is large enough to justify using relativity, but for simplicity do this as a nonrelativistic calculation.)
   b. Figure 39.13 is greatly magnified. What was the actual spacing on the detector between adjacent bright fringes?

45. The neutron interference pattern of FIGURE P39.45 was made by shooting neutrons with a speed of 200 m/s through two slits spaced 0.10 mm apart.
   a. What was the energy, in eV, of the neutrons?
   b. What was the de Broglie wavelength of the neutrons?
   c. The pattern was recorded by using a neutron detector to measure the neutron intensity at different positions. Notice the 100 μm scale on the figure. By making appropriate measurements directly *on the figure,* determine how far the detector was behind the slits.

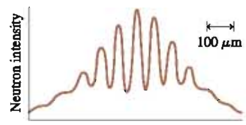

FIGURE P39.45

46. The electron beam in a cathode-ray tube is accelerated through a potential difference of 250 V. The electrons then pass through a small circular hole and are viewed on the screen. You observe that the central bright spot on the screen is the base of a cone with its apex at the hole. The outer edge of the cone makes a 0.50° angle with the original direction of the electron beam. What is the diameter of the hole?

47. An electron confined in a one-dimensional box is observed, at different times, to have energies of 12 eV, 27 eV, and 48 eV. What is the length of the box?

48. An electron confined in a one-dimensional box emits a 200 nm photon in a quantum jump from $n = 2$ to $n = 1$. What is the length of the box?

49. A proton confined in a one-dimensional box emits a 2.0 MeV gamma-ray photon in a quantum jump from $n = 2$ to $n = 1$. What is the length of the box?

50. The absorption spectrum of an atom consists of the wavelengths 200 nm, 300 nm, and 500 nm.
   a. Draw the atom's energy-level diagram.
   b. What wavelengths are seen in the atom's emission spectrum?

51. The first three energy levels of the fictitious element X are shown in FIGURE P39.51.
   a. What is the ionization energy of element X?
   b. What wavelengths are observed in the absorption spectrum of element X? Express your answers in nm.

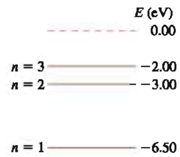

FIGURE P39.51

   c. State whether each of your wavelengths in part b corresponds to ultraviolet, visible, or infrared light.
   d. An electron with a speed of 1.4×10^6 m/s collides with an atom of element X. Shortly afterward, the atom emits a 1240 nm photon. What was the electron's speed after the collision? Assume that, because the atom is so much more massive than the electron, the recoil of the atom is negligible.

Hint: The energy of the photon is *not* the energy transferred to the atom in the collision.

52. Starting from Equation 39.28, derive Equation 39.29.

53. What is the energy of a hydrogen atom with a 5.18 nm diameter?

54. Calculate *all* the wavelengths of *visible* light in the emission spectrum of the hydrogen atom.
Hint: There are infinitely many wavelengths in the spectrum, so you'll need to develop a strategy for this problem rather than using trial and error.

55. A hydrogen atom in the ground state absorbs a 13.06 eV photon. Immediately after the absorption, the atom undergoes a quantum jump with $\Delta n = 2$. What is the wavelength of the photon emitted in this quantum jump?

56. a. What wavelength photon does a hydrogen atom emit in a $200 \rightarrow 199$ transition?
   b. What is the *difference* in the wavelengths emitted in a $199 \rightarrow 2$ transition and a $200 \rightarrow 2$ transition?

57. a. Calculate the orbital radius and the speed of an electron in both the $n = 99$ and the $n = 100$ states of hydrogen.
   b. Determine the orbital frequency of the electron in each of these states.
   c. Calculate the frequency of a photon emitted in a $100 \rightarrow 99$ transition.
   d. Compare the photon frequency of part c to the *average* of your two orbital frequencies from part b. By what percent do they differ?

58. Draw an energy-level diagram, similar to Figure 39.24, for the He^+ ion. On your diagram:
   a. Show the first five energy levels. Label each with the values of n and E_n.
   b. Show the ionization limit.
   c. Show all possible emission transitions from the $n = 4$ energy level.
   d. Calculate the wavelengths (in nm) for each of the transitions in part c and show them alongside the appropriate arrow.

59. What are the wavelengths of the transitions $3 \rightarrow 2$, $4 \rightarrow 2$, and $5 \rightarrow 2$ in the hydrogen-like ion O^{+7}? In what spectral range do these lie?

60. Two hydrogen atoms collide head-on. The collision brings both atoms to a halt. Immediately after the collision, both atoms emit a 121.6 nm photon. What was the speed of each atom just before the collision?

61. A beam of electrons is incident upon a gas of hydrogen atoms.
   a. What minimum speed must the electrons have to cause the emission of 656 nm light from the $3 \rightarrow 2$ transition of hydrogen?
   b. Through what potential difference must the electrons be accelerated to have this speed?

Challenge Problems

62. The photomultiplier tube (PMT) of Figure 39.12a consists of a cathode, which the photon strikes; an anode, where the electrons are collected; and a number of intermediate electrodes called *dynodes.* The tube shown in the figure has nine dynodes, but consider a PMT with N dynodes. The cathode, when struck by a photon, ejects a single photoelectron. That electron is accelerated to the first dynode, where it causes (on average) the ejection of ϵ secondary electrons. The quantity ϵ is called the *secondary emission coefficient.* Each of these electrons ejects, on average, ϵ electrons from the second dynode, each of which in turn ejects ϵ electrons from the third dynode, and so on until a large pulse of electrons is collected by the anode.
    a. Write an expression, in terms of ϵ and N, for the average number of electrons arriving at the anode due to a single photon striking the cathode. This is called the *gain* of the PMT.
    b. The graph in Figure 39.12b shows the voltage pulse generated when the electron current flowed through a 50 Ω resistor. The baseline of the pulse is zero volts, and the voltage scale is 20 mV per division. What is the maximum *current* of this pulse?
    c. Because $I = dQ/dt$, the amount of charge delivered by a pulse of current is $Q = \int I dt$. This can be interpreted geometrically as the area under the I-versus-t curve. The area of a pulse is reasonably well approximated as its height multiplied by its width measured at half of its maximum height. Estimate the number of electrons in the current pulse shown in Figure 39.12b.
    d. The PMT that produced this pulse had 14 dynodes. By comparing your answers to parts a and c, determine the secondary emission coefficient for this PMT.
63. Ultraviolet light with a wavelength of 70.0 nm shines on a gas of hydrogen atoms in their ground states. Some of the atoms are ionized by the light. What is the kinetic energy of the electrons that are freed in this process?
64. In the atom interferometer experiment of Figure 39.14, laser-cooling techniques were used to cool a dilute vapor of sodium atoms to a temperature of 0.0010 K = 1.0 mK. The ultracold atoms passed through a series of collimating apertures to form the *atomic beam* you see entering the figure from the left. The standing light waves were created from a laser beam with a wavelength of 590 nm.
    a. What is the rms speed v_{rms} of a sodium atom ($A = 23$) in a gas at temperature 1.0 mK?
    b. By treating the laser beam as if it were a diffraction grating, calculate the first-order diffraction angle of a sodium atom traveling with the rms speed of part a.
    c. How far apart are points B and C if the second standing wave is 10 cm from the first?
    d. Because interference is observed between the two paths, each individual atom is apparently present at both point B *and* point C. Describe, in your own words, what this experiment tells you about the nature of matter.
65. Consider a hydrogen atom in stationary state n.
    a. Show that the orbital period of the electron is $T = n^3 T_1$, and find a numerical value for T_1.
    b. On average, an atom stays in the $n = 2$ state for 1.6 ns before undergoing a quantum jump to the $n = 1$ state. On average, how many revolutions does the electron make before the quantum jump?
66. Consider an electron undergoing cyclotron motion in a magnetic field. According to Bohr, the electron's angular momentum must be quantized in units of $\hbar$.
    a. Show that allowed radii for the electron's orbit are given by $r_n = (n\hbar/eB)^{1/2}$, where $n = 1, 2, 3, \ldots$.
    b. Compute the first four allowed radii in a 1.0 T magnetic field.
    c. Find an expression for the allowed energy levels E_n in terms of $\hbar$ and the cyclotron frequency f_{cyc}.
67. The *muon* is a subatomic particle with the same charge as an electron but with a mass that is 207 times greater: $m_\mu = 207 m_e$. Physicists think of muons as "heavy electrons." However, the muon is not a stable particle; it decays with a half-life of 1.5 μs into an electron plus two neutrinos. Muons from cosmic rays are sometimes "captured" by the nuclei of the atoms in a solid. A captured muon orbits this nucleus, like an electron, until it decays. Because the muon is often captured into an excited orbit ($n > 1$), its presence can be detected by observing the photons emitted in transitions such as $2 \to 1$ and $3 \to 1$.

    Consider a muon captured by a carbon nucleus ($Z = 6$). Because of its large mass, the muon orbits well *inside* the electron cloud and is not affected by the electrons. Thus the muon "sees" the full nuclear charge Ze and acts like the electron in a hydrogen-like ion.
    a. What are the orbital radius and speed of a muon in the $n = 1$ ground state? Note that the mass of a muon differs from the mass of an electron.
    b. What is the wavelength of the $2 \to 1$ muon transition?
    c. Is the photon emitted in the $2 \to 1$ transition infrared, visible, ultraviolet, or x ray?
    d. How many orbits will the muon complete during 1.5 μs? Is this a sufficiently large number that the Bohr model "makes sense," even though the muon is not stable?

STOP TO THINK ANSWERS

Stop to Think 39.1: $V_A > V_B > V_C$. For a given wavelength of light, electrons are ejected with more kinetic energy from metals with smaller work functions because it takes less energy to remove an electron. Faster electrons need a larger negative voltage to stop them.

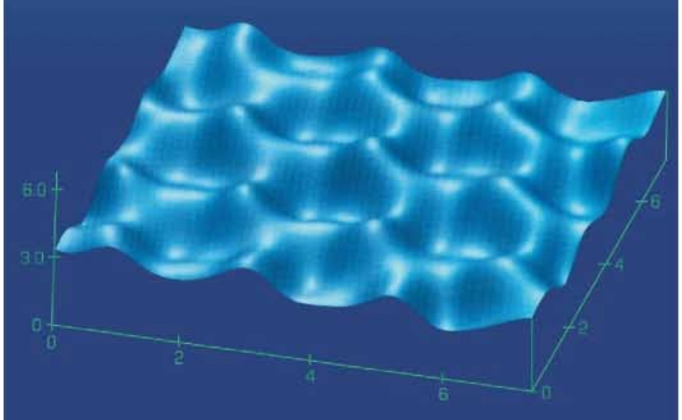
Stop to Think 39.2: d. Photons always travel at c, and a photon's energy depends only on the light's frequency, not its intensity.

Stop to Think 39.3: $n = 4$. There are four antinodes.

Stop to Think 39.4: Not in absorption. In emission from the $n = 2$ to $n = 1$ transition. The photon energy has to match the energy *difference* between two energy levels. Absorption is from the ground state, at $E_1 = 0.00$ eV. There's no energy level at 3.00 eV to which the atom could jump.

Stop to Think 39.5: $n = 3$. Each antinode is half a wavelength, so this standing wave has three full wavelengths in one circumference.

40 Wave Functions and Uncertainty



The surface of graphite, as imaged with atomic resolution by a scanning tunneling microscope. The hexagonal ridges show the most probable locations of the electrons.

► Looking Ahead

The goal of Chapter 40 is to introduce the wave-function description of matter and learn how it is interpreted. In this chapter you will learn to:

- Connect the particle and wave descriptions of matter.
- Use basic ideas about probability.
- Use the wave function to calculate the probabilities of detecting particles.
- Recognize the limitations on knowledge imposed by the Heisenberg uncertainty principle.

◄ Looking Back

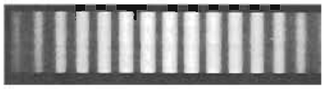
The ideas developed in this chapter are highly dependent on understanding the double-slit interference experiment for both light and matter. Please review:

- Sections 21.8 and 22.2 Interference, beats, and the double-slit experiment.
- Sections 25.3 and 39.3 Photons.
- Sections 25.4 and 39.4 Matter waves, the de Broglie wavelength, and wave–particle duality.

You learned in the last two chapters that classical mechanics and electromagnetism were unable to explain the new phenomena associated with light, electrons, and atoms. Scientific theories that had triumphed during the 18th and 19th centuries stumbled over the smallest specks of matter. Many scientists refused to accept these limitations, thinking that it was only a question of time until someone discovered how to apply classical ideas to atoms. Their hopes were to go unfulfilled.

At the same time that classical physics was reaching its limits, the new ideas put forward by Einstein, Bohr, and de Broglie began pointing the way toward a new theory of light and matter. **Quantum mechanics,** as the theory came to be called, did not reach its completed form until the mid-1920s, but it has since proven to be the most successful physical theory ever devised.

This chapter and the next will introduce the essential ideas of quantum mechanics in one dimension. Although the full theory is beyond the scope of this textbook, we can delve far enough into quantum mechanics to learn how it solves the problems of atomic and nuclear structure. Our goal in this chapter is to introduce the concept of the *wave function.* The wave function, which reconciles the wave-like and particle-like aspects of matter, characterizes microscopic particles in terms of the *probability* of finding them at various points in space. The scanning tunneling microscope image of graphite seen above shows that the most probable place to find electrons is along the ring-like structures created by the carbon-carbon bonds.



Interference fringes in an optical double-slit interference experiment.

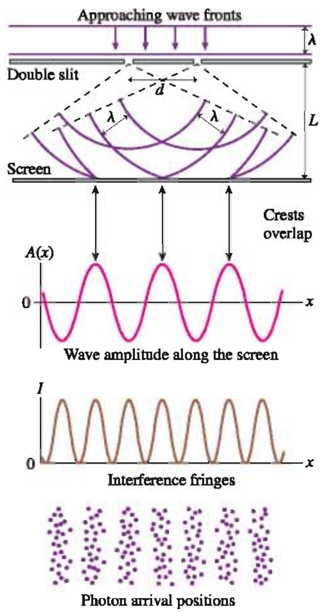
40.1 Waves, Particles, and the Double-Slit Experiment

You may feel surprise at how slowly we have been building up to quantum mechanics. Why not just write it down and start using it? There are two reasons. First, quantum mechanics explains microscopic phenomena that we cannot directly sense or experience. It was important to begin by learning how light and atoms behave. Otherwise, how would you know if quantum mechanics explains anything? Second, the concepts we'll need in quantum mechanics are rather abstract. Before launching into the mathematics, we need to establish a connection between theory and experiment.

We will make the connection by returning to the double-slit interference experiment, an experiment that goes right to the heart of wave–particle duality. The significance of the double-slit experiment arises from the fact that both light and matter exhibit the same interference pattern. Regardless of whether photons, electrons, or neutrons pass through the slits, their arrival at a detector is a particle-like event. That is, they make a collection of discrete dots on a detector. Yet our understanding of how interference "works" is based on the properties of waves. Our goal is to find the connection between the wave description and the particle description of interference.

A Wave Analysis of Interference

FIGURE 40.1 The double-slit experiment with light.



The interference of light can be analyzed from either a wave perspective or a photon perspective. Let's start with a wave analysis. FIGURE 40.1 shows light waves passing through a double slit with slit separation d. You should recall that the lines in a wave-front diagram represent wave crests, spaced one wavelength apart. The bright fringes of constructive interference occur where two crests or two troughs overlap. The graphs and picture below the detection screen (notice that they're aligned vertically) show the outcome of the experiment.

You studied interference and the double-slit experiment in Chapters 21 and 22. The two waves traveling from the slits to the viewing screen are traveling waves with displacements

$$D_1 = a\sin(kr_1 - \omega t)$$
$$D_2 = a\sin(kr_2 - \omega t)$$

where a is the amplitude of each wave, $k = 2\pi/\lambda$ is the wave number, and r_1 and r_2 are the distances from the two slits. The "displacement" of a light wave is not a physical displacement, as in a water wave, but a change in the electromagnetic field.

According to the principle of superposition, these two waves add together where they meet at a point on the screen to give a wave with net displacement $D = D_1 + D_2$. Previously (see Equation 22.12) we found that the amplitude of their superposition is

$$A(x) = 2a\cos\left(\frac{\pi d x}{\lambda L}\right) \tag{40.1}$$

where x is the horizontal coordinate on the screen, measured from $x = 0$ in the center.

The function $A(x)$, the top graph in Figure 40.1, is called the *amplitude function.* It describes the amplitude A of the light wave as a function of the position x on the viewing screen. The amplitude function has maxima where two crests from individual waves overlap and add constructively to make a larger wave with amplitude $2a$. $A(x)$ is zero at points where the two individual waves are out of phase and interfere destructively.

If you carry out a double-slit experiment in the lab, what you observe on the screen is the light's *intensity,* not its amplitude. A wave's intensity I is proportional to the *square* of the amplitude. That is, $I \propto A^2$, where $\propto$ is the "is proportional to" symbol.

Using Equation 40.1 for the amplitude at each point, we find the intensity $I(x)$ as a function of position x on the screen is

$$I(x) = C\cos^2\left(\frac{\pi d x}{\lambda L}\right) \tag{40.2}$$

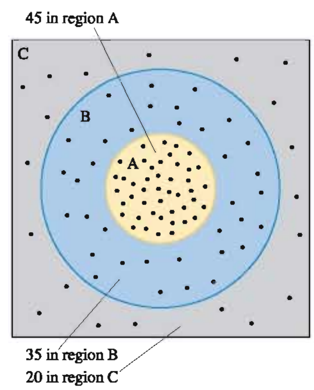
where C is a proportionality constant.

The lower graph in Figure 40.1 shows the intensity as a function of position along the screen. This graph shows the alternating bright and dark interference fringes that you see in the laboratory. In other words, the intensity of the wave is the *experimental reality* that you observe and measure.

Probability

Before discussing photons, we need to introduce some ideas about probability. Imagine throwing darts at a dart board while blindfolded. **FIGURE 40.2** shows how the board might look after your first 100 throws. From this information, can you predict where your 101st throw is going to land? We'll assume that all darts hit the board.

FIGURE 40.2 One hundred throws at a dart board.



No. The position of any individual dart is *unpredictable.* No matter how hard you try to reproduce the previous throw, a second dart will not land at the same place. Yet there is clearly an overall *pattern* to the where the darts strike the board. Even blindfolded, you had a general sense of where the center of the board was, so each dart was *more likely* to land near the center than at the edge.

Although we can't predict where any individual dart will land, we can use the information in Figure 40.2 to determine the *probability* that your next throw will land in region A or region B or region C. Because 45 out of 100 throws landed in region A, we could say that the *odds* of hitting region A are 45 out of 100, or 45%.

Now, 100 throws isn't all that many. If you throw another 100 darts, perhaps only 43 will land in region A. Then maybe 48 of the next 100 throws. Imagine that the total number of throws N_{tot} becomes extremely large. Then the **probability** that any particular throw lands in region A is defined to be

$$P_A = \lim_{N_{tot}\to\infty} \frac{N_A}{N_{tot}} \tag{40.3}$$

In other words, the probability that the outcome will be A is the fraction of outcomes that are A in an enormously large number of trials. Similarly, $P_B = N_B/N_{tot}$ and $P_C = N_C/N_{tot}$ as $N_{tot} \to \infty$. We can give probabilities as either a decimal fraction or a percentage. In this example, $P_A \approx 45\%$, $P_B \approx 35\%$, and $P_C \approx 20\%$. We've used $\approx$ rather than $=$ because 100 throws isn't enough to determine the probabilities with great precision.

What is the probability that a dart lands in either region A *or* region B? The number of darts landing in either A *or* B is $N_{A\text{ or }B} = N_A + N_B$, so we can use the definition of probability to learn that

$$\begin{aligned} P_{A\text{ or }B} &= \lim_{N_{tot}\to\infty} \frac{N_{A\text{ or }B}}{N_{tot}} = \lim_{N_{tot}\to\infty} \frac{N_A + N_B}{N_{tot}} \\ &= \lim_{N_{tot}\to\infty} \frac{N_A}{N_{tot}} + \lim_{N_{tot}\to\infty} \frac{N_B}{N_{tot}} = P_A + P_B \end{aligned} \tag{40.4}$$

That is, **the probability that the outcome will be A *or* B is the sum of P_A and P_B.** This important conclusion is a general property of probabilities.

Each dart lands *somewhere on* the board. Consequently, the probability that a dart lands in A *or* B *or* C must be 100%. And, in fact,

$$P_{somewhere} = P_{A\text{ or }B\text{ or }C} = P_A + P_B + P_C = 0.45 + 0.35 + 0.20 = 1.00$$

Thus another important property of probabilities is that **the sum of the probabilities of all possible outcomes must equal 1.**

Suppose exhaustive trials have established that the probability of a dart landing in region A is P_A. If you throw N darts, how many do you *expect* to land in A? This value, called the **expected value,** is

$$N_{A\,expected} = NP_A \tag{40.5}$$

The expected value is your best possible prediction of the outcome of an experiment.

If $P_A = 0.45$, your *best prediction* is that 27 of 60 throws (45% of 60) will land in A. Of course, predicting 27 and actually getting 27 aren't the same thing. You would predict 30 heads in 60 flips of a coin, but you wouldn't be surprised if the actual number were 28 or 31. Similarly, the number of darts landing in region A might be 24 or 29 instead of 27. In general, the agreement between actual values and expected values improves as you throw more darts.

STOP TO THINK 40.1 Suppose you roll a die 30 times. What is the expected number of 1's *and* 6's?

A Photon Analysis of Interference

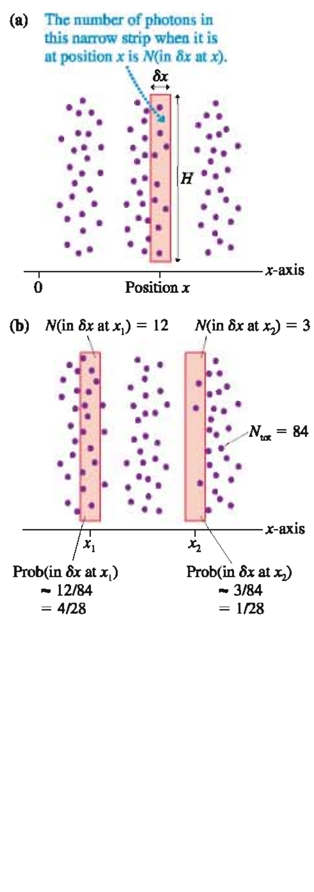
Now let's look at the double-slit results from a photon perspective. We know, from experimental evidence, that the interference pattern is built up photon by photon. The bottom portion of Figure 40.1 shows the pattern made on a detector after the arrival of the first few dozen photons. It is clearly a double-slit interference pattern, but it's made, rather like a newspaper photograph, by piling up dots in some places but not others.

The arrival position of any particular photon is *unpredictable*. That is, nothing about how the experiment is set up or conducted allows us to predict exactly where the dot of an individual photon will appear on the detector. Yet there is clearly an overall pattern. There are some positions at which a photon is *more likely* to be detected, other positions at which it is *less likely* to be found.

If we record the arrival positions of many thousands of photons, we will be able to determine the *probability* that a photon will be detected at any given location. If 50 out of 50,000 photons land in one small area of the screen, then each photon has a probability of 50/50,000 = 0.001 = 0.1% of being detected there. The probability will be zero at the interference minima because no photons at all arrive at those points. Similarly, the probability will be a maximum at the interference maxima. The probability will have some in-between value on the sides of the interference fringes.

FIGURE 40.3a shows a narrow strip with width δx and height H. (We will assume that δx is very small in comparison with the fringe spacing, so the light's intensity over δx is very nearly constant.) Think of this strip as a very narrow detector that can detect and count the photons landing on it. Suppose we place the narrow strip at position x. We'll use the notation $N(\text{in } \delta x \text{ at } x)$ to indicate the number of photons that hit the detector at this position. The value of $N(\text{in } \delta x \text{ at } x)$ varies from point to point. $N(\text{in } \delta x \text{ at } x)$ is large if x happens to be near the center of a bright fringe; $N(\text{in } \delta x \text{ at } x)$ is small if x is in a dark fringe.

FIGURE 40.3 A strip of width δx at position x.



Suppose N_{tot} photons are fired at the slits. The *probability* that any one photon ends up in the strip at position x is

$$\text{Prob}(\text{in } \delta x \text{ at } x) = \lim_{N_{tot}\to\infty} \frac{N(\text{in } \delta x \text{ at } x)}{N_{tot}} \tag{40.6}$$

As **FIGURE 40.3b** shows, Equation 40.6 is an empirical method for determining the probability of the photons hitting a particular spot on the detector.

Alternatively, suppose we can calculate the probabilities from a theory. In that case, the *expected value* for the number of photons landing in the narrow strip when it is at position x is

$$N(\text{in } \delta x \text{ at } x) = N \times \text{Prob}(\text{in } \delta x \text{ at } x) \tag{40.7}$$

We cannot predict what any individual photon will do, but we can predict the fraction of the photons that should land in this little region of space. Prob(in δx at x) is the probability that it will happen.

40.2 Connecting the Wave and Photon Views

The wave model of light describes the interference pattern in terms of the wave's intensity $I(x)$, a continuous-valued function. The photon model describes the interference pattern in terms of the probability Prob(in δx at x) of detecting a photon. These two models are very different, yet Figure 40.1 shows a clear correlation between the *intensity of the wave* and the *probability of detecting photons*. That is, photons are more likely to be detected at those points where the wave intensity is high and less likely to be detected at those points where the wave intensity is low.

The intensity of a wave is $I = P/A$, the ratio of light power P (joules per second) to the area A on which the light falls. The narrow strip in Figure 40.3a has area $A = H\delta x$. If the light intensity at position x is $I(x)$, the amount of light energy falling onto this narrow strip during each second is

$$E(\text{in } \delta x \text{ at } x) = I(x)A = I(x)H\delta x \tag{40.8}$$

The notation $E(\text{in } \delta x \text{ at } x)$ refers to the energy landing on this narrow strip if you place it at position x.

From the photon perspective, energy E is due to the arrival of N photons, each of which has energy hf. The number of photons that arrive in the strip each second is

$$N(\text{in } \delta x \text{ at } x) = \frac{E(\text{in } \delta x \text{ at } x)}{hf} = \frac{H}{hf}I(x)\delta x \tag{40.9}$$

We can then use the Equation 40.6 definition of probability to write the *probability* that a photon lands in the narrow strip δx at position x as

$$\text{Prob}(\text{in } \delta x \text{ at } x) = \frac{N(\text{in } \delta x \text{ at } x)}{N_{\text{tot}}} = \frac{H}{hfN_{\text{tot}}}I(x)\delta x \tag{40.10}$$

Equation 40.10 is a critical link between the wave model and the photon model.

As a final step, recall that the light intensity $I(x)$ is proportional to $|A(x)|^2$, the square of the amplitude function. Consequently,

$$\boxed{\text{Prob}(\text{in } \delta x \text{ at } x) \propto |A(x)|^2\delta x} \tag{40.11}$$

where the various constants in Equation 40.10 have all been incorporated into the unspecified proportionality constant of Equation 40.11.

In other words, **the probability of detecting a photon at a particular point is directly proportional to the square of the light-wave amplitude function at that point.** If the wave amplitude at point A is twice that at point B, then a photon is four times as likely to land in a narrow strip at A as it is to land in an equal-width strip at B.

NOTE ▶ Equation 40.11 is the connection between the particle perspective and the wave perspective. It relates the probability of observing a particle-like event—the arrival of a photon—to the amplitude of a continuous, classical wave. This connection will become the basis of how we interpret the results of quantum-physics calculations. ◀

Probability Density

We need one last definition. Recall that the mass of a wire or string of a length L can be expressed in terms of the linear mass density μ as $m = \mu L$. Similarly, the charge along a length L of wire can be expressed in terms of the linear charge density λ as $Q = \lambda L$. If the length had been very short—in which case we might have denoted it as δx,—and if the density varied from point to point, we could have written

$$\text{mass(in length } \delta x \text{ at } x) = \mu(x)\,\delta x$$

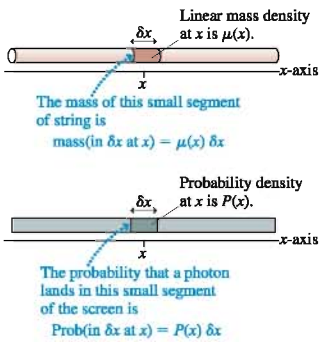
$$\text{charge(in length } \delta x \text{ at } x) = \lambda(x)\,\delta x$$

where $\mu(x)$ and $\lambda(x)$ are the linear densities at position x. Writing the mass and charge this way separates the role of the density from the role of the small length δx.

Equation 40.11 looks similar. Using the mass and charge densities as analogies, as shown in FIGURE 40.4, we can define the **probability density** $P(x)$ such that

$$\boxed{\text{Prob(in } \delta x \text{ at } x) = P(x)\,\delta x} \quad (40.12)$$

FIGURE 40.4 The probability density is analogous to the linear mass density.



In one dimension, probability density has SI units of m^{-1}. Thus the probability density multiplied by a length, as in Equation 40.12, yields a dimensionless probability.

NOTE ► $P(x)$ itself is *not* a probability, just as the linear mass density λ is not, by itself, a mass. You must multiply the probability density by a length, as shown in Equation 40.12, to find an actual probability. ◄

By comparing Equation 40.12 to Equation 40.11, you can see that the photon probability density is directly proportional to the square of the light-wave amplitude:

$$P(x) \propto |A(x)|^2 \quad (40.13)$$

The probability density, unlike the probability itself, is independent of the width δx and depends on only the position x.

Although we were inspired by the double-slit experiment, nothing in our analysis actually depends on the double-slit geometry. Consequently, Equation 40.13 is quite general. It says that for *any* experiment in which we detect photons, **the probability density for detecting a photon is directly proportional to the square of the amplitude function of the corresponding electromagnetic wave.** We now have an explicit connection between the wave-like and the particle-like properties of the light.

EXAMPLE 40.1 Calculating the probability density

In an experiment, 6000 out of 600,000 photons are detected in a 1.0-mm-wide strip located at position $x = 50$ cm. What is the probability density at $x = 50$ cm?

SOLVE The probability that a photon arrives at this particular strip is

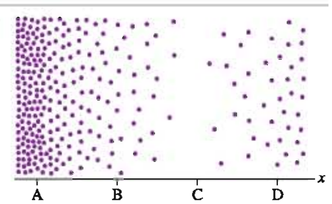
$$\text{Prob(in 1.0 mm at } x = 50 \text{ cm}) = \frac{6000}{600{,}000} = 0.010$$

Thus the probability density $P(x) = \text{Prob(in } \delta x \text{ at } x)/\delta x$ at this position is

$$P(50 \text{ cm}) = \frac{\text{Prob(in 1.0 mm at } x = 50 \text{ cm})}{0.0010 \text{ m}} = \frac{0.010}{0.0010 \text{ m}}$$

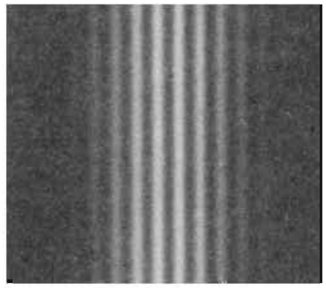
$$= 10 \text{ m}^{-1}$$

STOP TO THINK 40.2 The figure shows the detection of photons in an optical experiment. Rank in order, from largest to smallest, the square of the amplitude function of the electromagnetic wave at positions A, B, C, and D.



40.3 The Wave Function

Now let's look at the interference of matter. Electrons passing through a double-slit apparatus create the same interference patterns as photons. The pattern is built up electron by electron, but there is no way to predict where any particular electron will be detected. Even so, we can establish the *probability* of an electron landing in a narrow strip of width δx by measuring the positions of many individual electrons.



Electrons create interference fringes after passing through a double slit.

For light, we were able to relate the photon probability density $P(x)$ to the amplitude of an electromagnetic wave. But there is no wave for electrons like electromagnetic waves for light. So how do we find the probability density for electrons? We have reached the point where we must make an inspired leap beyond classical physics. Let us *assume* that there is some kind of continuous, wave-like function for matter that plays a role analogous to the electromagnetic amplitude function $A(x)$ for light. We will call this function the **wave function** $\psi(x)$, where ψ is a lowercase Greek psi. The wave function is a function of position, which is why we write it as $\psi(x)$.

To connect the wave function to the real world of experimental measurements, we will interpret $\psi(x)$ in terms of the *probability* of detecting a particle at position x. If a matter particle, such as an electron, is described by the wave function $\psi(x)$, then the probability Prob(in δx at x) of finding the particle within a narrow region of width δx at position x is

$$\text{Prob(in } \delta x \text{ at } x) = |\psi(x)|^2 \delta x = P(x)\,\delta x \tag{40.14}$$

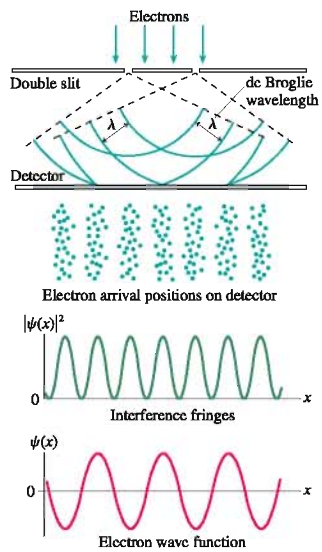
That is, the probability density $P(x)$ for finding the particle is

$$P(x) = |\psi(x)|^2 \tag{40.15}$$

With Equations 40.14 and 40.15, we are *defining* the wave function $\psi(x)$ to play the same role for material particles that the amplitude function $A(x)$ does for photons. The only difference is that $P(x) = |\psi(x)|^2$ is for particles, whereas Equation 40.13 for photons is $P(x) \propto |A(x)|^2$. The difference is because that the electromagnetic field amplitude $A(x)$ had previously been defined through the laws of electricity and magnetism. $|A(x)|^2$ is *proportional* to the probability density for finding a photon, but it is not directly *the* probability density. In contrast, we do not have any preexisting definition for the wave function $\psi(x)$. Thus we are free to define $\psi(x)$ so that $|\psi(x)|^2$ is *exactly* the probability density. That is why we used $=$ rather than $\propto$ in Equation 40.15.

FIGURE 40.5 shows the double-slit experiment with electrons. This time we will work backward. From the observed distribution of electrons, which represents the probabilities of their landing in any particular location, we can deduce that $|\psi(x)|^2$ has alternating maxima and zeros. The oscillatory wave function $\psi(x)$ is the square root *at each point* of $|\psi(x)|^2$. Notice the very close analogy with the amplitude function $A(x)$ in Figure 40.1.

FIGURE 40.5 The double-slit experiment with electrons.



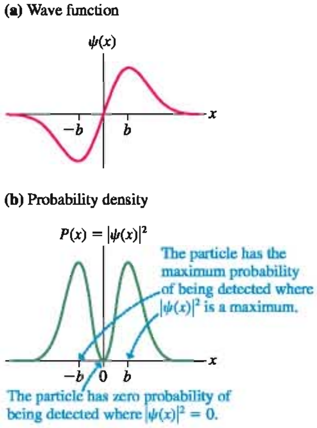
NOTE ▶ $|\psi(x)|^2$ is uniquely determined by the data, but the wave function $\psi(x)$ is *not* unique. The alternative wave function $\psi'(x) = -\psi(x)$—an upside-down version of the graph in Figure 40.5—would be equally acceptable. ◀

FIGURE 40.6a on the next page is a different example of a wave function. After squaring it *at each point,* as shown in **FIGURE 40.6b**, we see that this wave function represents a particle most likely to be detected very near $x = -b$ or $x = +b$. These are the points where $|\psi(x)|^2$ is a maximum. There is zero likelihood of finding the particle right in the center. The particle is more likely to be detected at some positions than at others, but we cannot predict its exact location.

NOTE ▶ One of the difficulties in learning to use the concept of a wave function is coming to grips with the fact that there is no "thing" that is waving. There is no disturbance associated with a physical medium. The wave function $\psi(x)$ is simply a *wave-like function* (i.e., it oscillates between positive and negative values) that can be used to make probabilistic predictions about atomic particles. ◀

A Little Science Methodology

FIGURE 40.6 The square of the wave function is the probability density for detecting the electron at various values of the position x.



Equation 40.14 defines the wave function $\psi(x)$ for a particle in terms of the probability of finding the particle at different positions x. But our interests go beyond merely characterizing experimental data. We would like to develop a new *theory* of matter. But just what is a theory? Although this is not a book on scientific methodology, we can loosely say that a physical theory needs two basic ingredients:

1. A *descriptor*, a mathematical quantity used to describe our knowledge of a physical object.
2. One or more *laws* that govern the behavior of the descriptor.

For example, Newtonian mechanics is a theory of motion. The primary descriptor in Newtonian mechanics is a particle's *position* $x(t)$ as a function of time. This describes our knowledge of the particle at all times. The position is governed by *Newton's laws*. These laws, especially the second law, are mathematical statements of how the descriptor changes in response to forces. If we predict $x(t)$ for a known set of forces, we feel confident that an experiment carried out at time t will find the particle right where predicted.

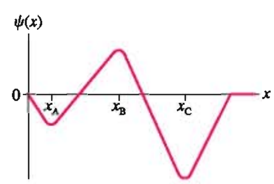
Newton's theory of motion *assumes* that a particle's position is well defined at every instant of time. The difficulty facing physicists early in the 20th century was the astounding discovery that **the position of an atomic-size particle is *not* well defined.** An electron in a double-slit experiment must, in some sense, go through *both* slits to produce an electron interference pattern. It simply does not have a well-defined position as it interacts with the slits. But if the position function $x(t)$ is not a valid descriptor for matter at the atomic level, what is?

We will assert that the wave function $\psi(x)$ is the *descriptor* of a particle in quantum mechanics. In other words, the wave function tells us everything we can know about the particle. The wave function $\psi(x)$ plays the same leading role in quantum mechanics that the position function $x(t)$ plays in classical mechanics.

Whether this hypothesis has any merit will not be known until we see if it leads to predictions that can be verified. And before we can do that, we need to learn the "law of psi." What new law of physics determines the wave function $\psi(x)$ in a given situation? We will answer this question in the next chapter.

It may seem to you, as we go along, that we are simply "making up" ideas. Indeed, that is at least partially true. The inventors of entirely new theories use their existing knowledge as a guide, but ultimately they have to make an inspired guess as to what a new theory should look like. Newton and Einstein both made such leaps, and the inventors of quantum mechanics had to make such a leap. We can attempt to make the new ideas *plausible*, but ultimately a new theory is simply a bold new assertion that must be tested against experimental reality. The wave-function theory of quantum mechanics passed the only test that really matters in science—it works!

STOP TO THINK 40.3 This is the wave function of a neutron. At what value of x is the neutron most likely to be found?

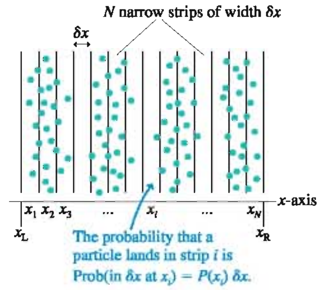


40.4 Normalization

In our discussion of probability we noted that the dart has to hit the wall *somewhere.* The mathematical statement of this idea is the requirement that $P_A + P_B + P_C = 1$. That is, the probabilities of all the mutually exclusive outcomes *must* add up to 1.

Similarly, a photon or electron has to land *somewhere* on the detector after passing through an experimental apparatus. Consequently, the probability that it will be detected at *some* position is 100%. To make use of this requirement, consider an experiment in which an electron is detected on the x-axis. As FIGURE 40.7 shows, we can divide the region between positions x_L and x_R into N adjacent narrow strips of width δx.

FIGURE 40.7 Dividing the entire detector into many small strips of width δx.



The probability that any particular electron lands in the narrow strip i at position x_i is

$$\text{Prob(in } \delta x \text{ at } x_i) = P(x_i)\,\delta x$$

where $P(x_i) = |\psi(x_i)|^2$ is the probability density at x_i. The probability that the electron lands in the strip at x_1 *or* x_2 *or* x_3 *or* . . . is the sum

$$\begin{aligned}\text{Prob(between } x_L \text{ and } x_R) &= \text{Prob(in } \delta x \text{ at } x_1) \\ &\quad + \text{Prob(in } \delta x \text{ at } x_2) + \cdots \\ &= \sum_{i=1}^{N} P(x_i)\,\delta x = \sum_{i=1}^{N} |\psi(x_i)|^2 \delta x\end{aligned} \tag{40.16}$$

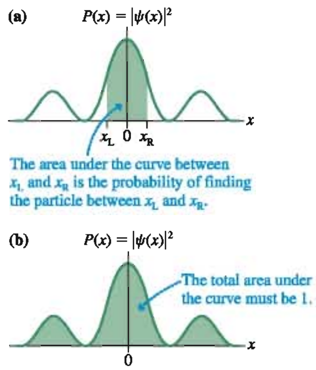
That is, **the probability that the electron lands *somewhere* between x_L and x_R is the sum of the probabilities of landing in each narrow strip.**

If we let the strips become narrower and narrower, then $\delta x \rightarrow dx$ and the sum becomes an integral. Thus the probability of finding the particles in the range $x_L \le x \le x_R$ is

$$\text{Prob(in range } x_L \le x \le x_R) = \int_{x_L}^{x_R} P(x)\,dx = \int_{x_L}^{x_R} |\psi(x)|^2 dx \tag{40.17}$$

As FIGURE 40.8a shows, we can interpret Prob(in range $x_L \le x \le x_R$) as the area under the probability density curve between x_L and x_R.

FIGURE 40.8 The area under the probability density curve is a probability.



NOTE ► The integral of Equation 40.17 is needed when the probability density changes over the range x_L to x_R. For sufficiently narrow intervals, over which $P(x)$ remains essentially constant, the expression Prob(in δx at x) $= P(x)\,\delta x$ is still valid and is easier to use. ◄

Now let the detector become infinitely wide, so that the probability that the electron will arrive *somewhere* on the detector becomes 100%. The statement that the electron has to land *somewhere* on the x-axis is expressed mathematically as

$$\int_{-\infty}^{\infty} P(x)\,dx = \int_{-\infty}^{\infty} |\psi(x)|^2 dx = 1 \tag{40.18}$$

Equation 40.18 is called the **normalization condition.** Any wave function $\psi(x)$ must satisfy this condition; otherwise we would not be able to interpret $|\psi(x)|^2$ as a probability density. As FIGURE 40.8b shows, Equation 40.18 tells us that the total area under the probability density curve must be 1.

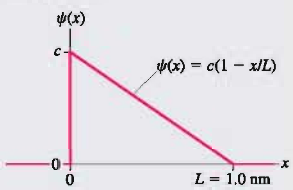
NOTE ► The normalization condition integrates the *square* of the wave function. We don't have any information about what the integral of $\psi(x)$ might be. ◄

EXAMPLE 40.2 Normalizing and interpreting a wave function

FIGURE 40.9 shows the wave function of a particle confined within the region between $x = 0$ nm and $x = L = 1.0$ nm. The wave function is zero outside this region.

a. Determine the value of the constant c.
b. Draw a graph of the probability density $P(x)$.
c. Draw a dot picture showing where the first 40 or 50 particles might be found.
d. Calculate the probability of finding the particle in a region of width $\delta x = 0.01$ nm at positions $x_1 = 0.05$ nm, $x_2 = 0.50$ nm, and $x_3 = 0.95$ nm.

FIGURE 40.9 The wave function of Example 40.2.



MODEL The probability of finding the particle is determined by the probability density $P(x)$.

VISUALIZE The wave function is shown in Figure 40.9.

SOLVE a. The wave function is $\psi(x) = c(1 - x/L)$ between 0 and L, 0 otherwise. This is a function that decreases linearly from $\psi = c$ at $x = 0$ to $\psi = 0$ at $x = L$. The constant c is the height of this wave function. The particle *has* to be in the region $0 \le x \le L$ with probability 1, and only one value of c will make it so. We can determine c by using Equation 40.18, the normalization condition. Because the wave function is zero outside the interval from 0 to L, the integration limits are 0 to L. Thus

$$1 = \int_0^L |\psi(x)|^2 dx = c^2 \int_0^L \left(1 - \frac{x}{L}\right)^2 dx$$

$$= c^2 \int_0^L \left(1 - \frac{2x}{L} + \frac{x^2}{L^2}\right) dx$$

$$= c^2 \left[x - \frac{x^2}{L} + \frac{x^3}{3L^2}\right]_0^L = \frac{1}{3} c^2 L$$

The solution for c is

$$c = \sqrt{\frac{3}{L}} = \sqrt{\frac{3}{1.0\text{ nm}}} = 1.732\text{ nm}^{-1/2}$$

Note the unusual units for c. Although these are not SI units, we can correctly compute probabilities as long as δx has units of nm. A multiplicative constant such as c is often called a *normalization constant.*

b. The wave function is

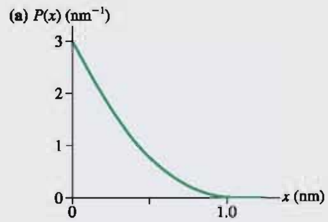
$$\psi(x) = (1.732\text{ nm}^{-1/2})\left(1 - \frac{x}{1.0\text{ nm}}\right)$$

Thus the probability density is

$$P(x) = |\psi(x)|^2 = (3.0\text{ nm}^{-1})\left(1 - \frac{x}{1.0\text{ nm}}\right)^2$$

This probability density is graphed in FIGURE 40.10a.

FIGURE 40.10 The probability density $P(x)$ and the detected positions of particles.



c. Particles are most likely to be detected at the left edge of the interval, where the probability density $P(x)$ is maximum. The probability steadily decreases across the interval, becoming zero at $x = 1.0$ nm. FIGURE 40.10b shows how a group of particles described by this wave function might appear on a detection screen.

d. $P(x)$ is essentially constant over the small interval $\delta x = 0.01$ nm, so we can use

$$\text{Prob(in } \delta x \text{ at } x) = P(x)\,\delta x = |\psi(x)|^2 \delta x$$

for the probability of finding the particle in a region of width δx at the position x. We need to evaluate $|\psi(x)|^2$ at the three positions $x_1 = 0.05$ nm, $x_2 = 0.50$ nm, and $x_3 = 0.95$ nm. Doing so gives

$$\text{Prob(in 0.01 nm at } x_1 = 0.05\text{ nm)} = c^2(1 - x_1/L)^2 \delta x = 0.0270 = 2.70\%$$

$$\text{Prob(in 0.01 nm at } x_2 = 0.50\text{ nm)} = c^2(1 - x_2/L)^2 \delta x = 0.0075 = 0.75\%$$

$$\text{Prob(in 0.01 nm at } x_3 = 0.95\text{ nm)} = c^2(1 - x_3/L)^2 \delta x = 0.00008 = 0.008\%$$

EXAMPLE 40.3 The probability of finding a particle

A particle is described by the wave function

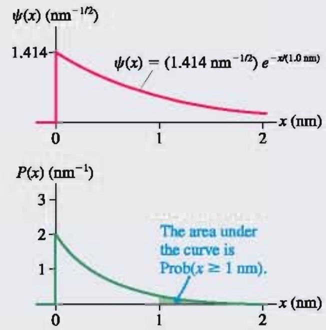
$$\psi(x) = \begin{cases} 0 & x < 0 \\ ce^{-x/L} & x \geq 0 \end{cases}$$

where $L = 1$ nm.

a. Determine the value of the constant c.
b. Draw graphs of $\psi(x)$ and the probability density $P(x)$.
c. Calculate the probability of finding the particle in the region $x \geq 1$ nm.

MODEL The probability of finding the particle is determined by the probability density $P(x)$.

FIGURE 40.11 The wave function and probability density of Example 40.3.



SOLVE a. The wave function is an exponential $\psi(x) = ce^{-x/L}$ that extends from $x = 0$ to $x = +\infty$. Equation 40.18, the normalization condition, is

$$1 = \int_{-\infty}^{\infty} |\psi(x)|^2 dx = c^2 \int_0^{\infty} e^{-2x/L} dx = -\frac{c^2 L}{2} e^{-2x/L}\Big|_0^{\infty} = \frac{c^2}{2L}$$

We can solve this for the normalization constant c:

$$c = \sqrt{\frac{2}{L}} = \sqrt{\frac{2}{1 \text{ nm}}} = 1.414 \text{ nm}^{-1/2}$$

b. The probability density is

$$P(x) = |\psi(x)|^2 = (2.0 \text{ nm}^{-1})e^{-2x/(1.0 \text{ nm})}$$

The wave function and the probability density are graphed in FIGURE 40.11.

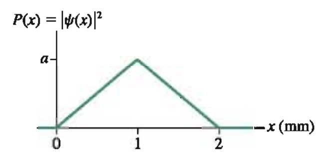
c. The probability of finding the particle in the region $x \geq 1$ nm is the shaded area under the probability density curve in Figure 40.11. We must use Equation 40.17 and integrate to find a numerical value. The probability is

$$\begin{aligned} \text{Prob}(x \geq 1 \text{ nm}) &= \int_{1 \text{ nm}}^{\infty} |\psi(x)|^2 dx \\ &= (2.0 \text{ nm}^{-1}) \int_{1 \text{ nm}}^{\infty} e^{-2x/(1.0 \text{ nm})} dx \\ &= (2.0 \text{ nm}^{-1}) \left(-\frac{1.0 \text{ nm}}{2}\right) e^{-2x/(1.0 \text{ nm})}\Big|_{1 \text{ nm}}^{\infty} \\ &= e^{-2} = 0.135 = 13.5\% \end{aligned}$$

ASSESS There is a 13.5% chance of finding the particle beyond 1 nm and thus an 86.5% chance of finding it within the interval $0 \leq x \leq 1$ nm. Unlike classical physics, we cannot make an exact prediction of the particle's position.

STOP TO THINK 40.4 The value of the constant a is

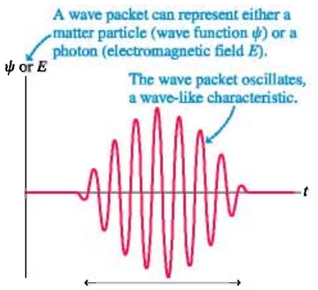
a. $a = 2.0 \text{ mm}^{-1}$
b. $a = 1.0 \text{ mm}^{-1}$
c. $a = 0.5 \text{ mm}^{-1}$
d. $a = 2.0 \text{ mm}^{-1/2}$
e. $a = 1.0 \text{ mm}^{-1/2}$
f. $a = 0.5 \text{ mm}^{-1/2}$



40.5 Wave Packets

The classical physics ideas of particles and waves are mutually exclusive. An object can be one or the other, but not both. These classical models fail to describe the wave–particle duality seen at the atomic level. An alternative model with both particle and wave characteristics is a *wave packet*.

FIGURE 40.12 History graph of a wave packet with duration Δt.



Consider the wave shown in FIGURE 40.12. Unlike the sinusoidal waves we have considered previously, which stretch through time and space, this wave is bunched up, or localized. The localization is a particle-like characteristic. The oscillations are wave-like. Such a localized wave is called a **wave packet**.

A wave packet travels through space with constant speed v, just like a photon in a light wave or an electron in a force-free region. A wave packet has a wavelength, hence it will undergo interference and diffraction. But because it is also localized, a wave packet has the possibility of making a "dot" when it strikes a detector. We can visualize a light wave as consisting of a very large number of these wave packets moving along together. Similarly, we can think of a beam of electrons as a series of wave packets spread out along a line.

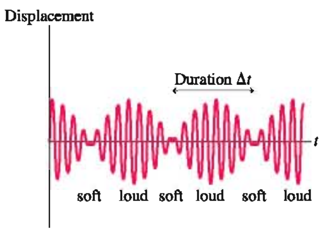
Wave packets are not a perfect model of photons or electrons (we need the full treatment of quantum physics to get a more accurate description), but they do provide a useful way of thinking about photons and electrons in many circumstances.

You might have noticed that the wave packet in Figure 40.12 looks very much like one cycle of a beat pattern. You will recall that beats occur if we superimpose two waves of frequencies f_1 and f_2 where the two frequencies are very similar: $f_1 \approx f_2$. FIGURE 40.13, which is copied from Chapter 21 where we studied beats, shows that the loud, soft, loud, soft, . . . pattern of beats corresponds to a series of wave packets.

In Chapter 21, the beat frequency (number of pulses per second) was found to be

$$f_{beat} = f_1 - f_2 = \Delta f \tag{40.19}$$

FIGURE 40.13 Beats are a series of wave packets.



where Δf is the *range* of frequencies that are superimposed to form the wave packet. Figure 40.13 defines Δt as the duration of each beat or each wave packet. This interval of time is equivalent to the *period* T_{beat} of the beat. Because period and frequency are inverses of each other, the duration Δt is

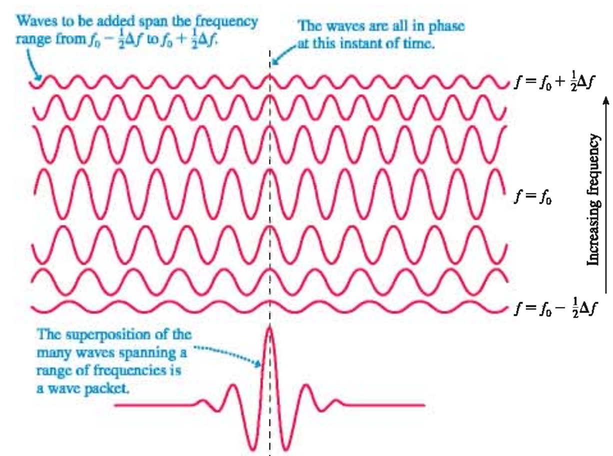
$$\Delta t = T_{beat} = \frac{1}{f_{beat}} = \frac{1}{\Delta f}$$

We can rewrite this as

$$\Delta f \Delta t = 1 \tag{40.20}$$

Equation 40.20 is nothing new; we are simply writing what we already knew in a different form. Equation 40.20 is a combination of three things: the relationship $f = 1/T$ between period and frequency, writing T_{beat} as Δt, and the specific knowledge that the beat frequency f_{beat} is the difference Δf of the two frequencies contributing to the wave packet. As the frequency separation gets smaller, the duration of each beat gets longer.

FIGURE 40.14 A single wave packet is the superposition of many component waves of similar wavelength and frequency.



When we superimpose two frequencies to create beats, the wave packet repeats over and over. A more advanced treatment of waves, called Fourier analysis, reveals that a single, *nonrepeating* wave packet can be created through the superposition of *many* waves of very similar frequency. FIGURE 40.14 illustrates this idea. At one instant of time, all the waves interfere constructively to produce the maximum amplitude of the wave packet. At other times, the individual waves get out of phase and their superposition tends toward zero.

Suppose a single nonrepeating wave packet of duration Δt is created by the superposition of *many* waves that span a range of frequencies Δf. We'll not prove it, but Fourier analysis shows that for *any* wave packet

$$\Delta f \Delta t \approx 1 \tag{40.21}$$

The relationship between Δf and Δt for a general wave packet is not as precise as Equation 40.20 for beats. There are two reasons for this:

1. Wave packets come in a variety of shapes. The exact relationship between Δf and Δt depends somewhat on the shape of the wave packet.
2. We have not given a precise definition of Δt and Δf for a general wave packet. The quantity Δt is "about how long the wave packet lasts," while Δf is "about the range of frequencies needing to be superimposed to produce this wave packet." For our purposes, we will not need to be any more precise than this.

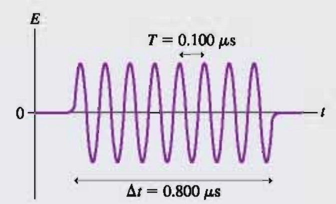
Equation 40.21 is a purely classical result that applies to waves of any kind. It tells you the range of frequencies you need to superimpose to construct a wave packet of duration Δt. Alternatively, Equation 40.21 tells you that a wave packet created as a superposition of various frequencies cannot be arbitrarily short but *must* last for a time interval $\Delta t \approx 1/\Delta f$.

EXAMPLE 40.4 Creating radio-frequency pulses

A short-wave radio station broadcasts at a frequency of 10.000 MHz. What is the range of frequencies of the waves that must be superimposed to broadcast a radio-wave pulse lasting 0.800 μs?

MODEL A pulse of radio waves is an electromagnetic wave packet, hence it must satisfy the relationship $\Delta f \Delta t \approx 1$.

FIGURE 40.15 A pulse of radio waves.



VISUALIZE FIGURE 40.15 shows the pulse.

SOLVE The period of a 10.000 MHz oscillation is 0.100 μs. A pulse 0.800 μs in duration is 8 oscillations of the wave. Although the station broadcasts at a nominal frequency of 10.000 MHz, this pulse is not a pure 10.000 MHz oscillation. Instead, the pulse has been created by the superposition of many waves whose frequencies span

$$\Delta f \approx \frac{1}{\Delta t} = \frac{1}{0.800 \times 10^{-6}\,\text{s}} = 1.250 \times 10^6\,\text{Hz} = 1.250\,\text{MHz}$$

This range of frequencies will be centered at the 10.000 MHz broadcast frequency, so the waves that must be superimposed to create this pulse span the frequency range

$$9.375\,\text{MHz} \le f \le 10.625\,\text{MHz}$$

Bandwidth

Short-duration pulses, like the one in Example 40.4, are used to transmit digital information. Digital signals are sent over a phone line by brief tone pulses, over satellite links by brief radio pulses like the one in the example, and through optical fibers by brief laser-light pulses. Regardless of the type of wave and the medium through which it travels, any wave pulse must obey the fundamental relationship $\Delta f \Delta t \approx 1$.

Sending data at a higher rate (i.e., more pulses per second) requires that the pulse duration Δt be shorter. But a shorter-duration pulse must be created by the superposition of a *larger* range of frequencies. Thus the medium through which a shorter-duration pulse travels must be physically able to transmit the full range of frequencies.

The range of frequencies that can be transmitted through a medium is called the **bandwidth** Δf_B of the medium. The shortest possible pulse that can be transmitted through a medium is

$$\Delta t_{min} \approx \frac{1}{\Delta f_B} \qquad (40.22)$$

A pulse shorter than this would require a larger range of frequencies than the medium can support.

The concept of bandwidth is extremely important in digital communications. A higher bandwidth permits the transmission of shorter pulses and allows a higher data rate. A standard telephone line does not have a very high bandwidth, and that is why a modem is limited to sending data at the rate of roughly 50,000 pulses per second. A 0.80 μs pulse can't be sent over a phone line simply because the phone line won't transmit the range of frequencies that would be needed.

An optical fiber is a high-bandwidth medium. A fiber has a bandwidth $\Delta f_B >$ 1 GHz and thus can transmit laser-light pulses with duration $\Delta t < 1$ ns. As a result, more than 10^9 pulses per second can be sent along an optical fiber, which is why optical-fiber networks form the backbone of the Internet.

Uncertainty

There is another way of thinking about the time-frequency relationship $\Delta f \Delta t \approx 1$. Suppose you want to determine *when* a wave packet arrives at a specific point in space, such as at a detector of some sort. At what instant of time can you say that the wave packet is detected? When the front edge arrives? When the maximum amplitude arrives? When the back edge arrives? Because a wave packet is spread out in time, there is not a unique and well-defined time t at which the packet arrives. All we can say is that it arrives within some interval of time Δt. We are *uncertain* about the exact arrival time.

Similarly, suppose you would like to know the oscillation frequency of a wave packet. There is no precise value for f because the wave packet is constructed from many waves within a range of frequencies Δf. All we can say is that the frequency is within this range. We are *uncertain* about the exact frequency.

The time-frequency relationship $\Delta f \Delta t \approx 1$ tells us that the uncertainty in our knowledge about the arrival time of the wave packet is related to our uncertainty about the packet's frequency. The more precisely and accurately we know one quantity, the less precisely we will be able to know the other.

FIGURE 40.16 Two wave packets with different Δt.

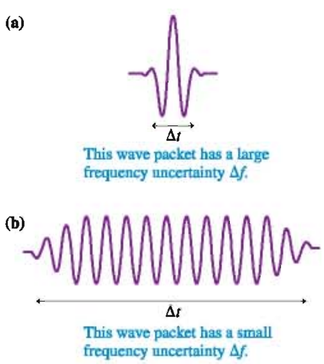


Figure 40.16 shows two different wave packets. The wave packet of **FIGURE 40.16a** is very narrow and thus very localized in time. As it travels, our knowledge of when it will arrive at a specified point is fairly precise. But a very wide range of frequencies Δf is required to create a wave packet with a very small Δt. The price we pay for being fairly certain about the time is a very large uncertainty Δf about the frequency of this wave packet.

FIGURE 40.16b shows the opposite situation: The wave packet oscillates many times and the frequency of these oscillations is pretty clear. Our knowledge of the frequency is good, with minimal uncertainty Δf. But such a wave packet is so spread out that there is a very large uncertainty Δt as to its time of arrival.

In practice, $\Delta f \Delta t \approx 1$ is really a lower limit. Technical limitations may cause the uncertainties in our knowledge of f and t to be even larger than this relationship implies. Consequently, a better statement about our knowledge of a wave packet is

$$\Delta f \Delta t \geq 1 \qquad (40.23)$$

The fact that waves are spread out makes it meaningless to specify an exact frequency

and an exact arrival time simultaneously. This is an inherent feature of waviness that applies to all waves.

STOP TO THINK 40.5 What minimum bandwidth must a medium have to transmit a 100-ns-long pulse?

a. 1 MHz b. 10 MHz c. 100 MHz d. 1000 MHz

40.6 The Heisenberg Uncertainty Principle

ActivPhysics ONLINE 17.6, 17.7

If matter has wave-like aspects and a de Broglie wavelength, then the expression $\Delta f \Delta t \geq 1$ must somehow apply to matter. How? And what are the implications?

Consider a particle with velocity v_x as it travels along the x-axis with deBroglie wavelength $\lambda = h/p_x$. Figure 40.12 showed a *history graph* (ψ versus t) of a wave packet that might represent the particle as it passes a point on the x-axis. It will be more useful to have a *snapshot graph* (ψ versus x) of the wave packet traveling along the x-axis.

The time interval Δt is the duration of the wave packet as the particle passes a point in space. During this interval, the packet moves forward

$$\Delta x = v_x \Delta t = \frac{p_x}{m}\Delta t \tag{40.24}$$

where $p_x = mv_x$ is the x-component of the particle's momentum. The quantity Δx, shown in FIGURE 40.17, is the length or spatial extent of the wave packet. Conversely, we can write the wave packet's duration in terms of its length as

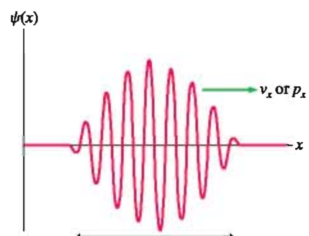

FIGURE 40.17 A snapshot graph of a wave packet.

$$\Delta t = \frac{m}{p_x}\Delta x \tag{40.25}$$

You will recall that any wave with sinusoidal oscillations must satisfy the wave condition $\lambda f = v$. For a material particle, where λ is the de Broglie wavelength, the frequency f is

$$f = \frac{v}{\lambda} = \frac{p_x/m}{h/p_x} = \frac{p_x^2}{hm}$$

A small range of frequencies Δf is related to a small range of momenta Δp_x by

$$\Delta f = \frac{2p_x \Delta p_x}{hm} \tag{40.26}$$

where we have assumed that $\Delta f \ll f$ and $\Delta p_x \ll p_x$ (a reasonable assumption) and thus treated the small ranges Δf and Δp_x as if they were differentials df and dp_x.

Multiplying together these expressions for Δt and Δf, we find that

$$\Delta f \Delta t = \frac{2p_x \Delta p_x}{hm}\frac{m\Delta x}{p_x} = \frac{2}{h}\Delta x \Delta p_x \tag{40.27}$$

Because $\Delta f \Delta t \geq 1$ for any wave, one last rearrangement of Equation 40.27 shows that a matter wave must obey the condition

$$\Delta x \Delta p_x \geq \frac{h}{2} \quad \text{(Heisenberg uncertainty principle)} \tag{40.28}$$

This statement about the relationship between the position and momentum of a particle was proposed by Werner Heisenberg, creator of one of the first successful quantum theories. Physicists often just call it the **uncertainty principle.**

NOTE ▶ In statements of the uncertainty principle, the right side is sometimes $h/2$, as we have it, but other times it is just h or contains various factors of π. The specific number is not especially important because it depends on exactly how Δx and Δp are defined. The important idea is that the product of Δx and Δp_x for a particle cannot be significantly less than Planck's constant h. A similar relationship for $\Delta y \Delta p_y$ applies along the y-axis. ◀

What Does It Mean?

Heisenberg's uncertainty principle is a statement about our *knowledge* of the properties of a particle. If we want to know *where* a particle is located, we measure its position x. That measurement is not absolutely perfect but has some uncertainty Δx. Likewise, if we want to know *how fast* the particle is going, we need to measure its velocity v_x or, equivalently, its momentum p_x. This measurement also has some uncertainty Δp_x.

Uncertainties are associated with all experimental measurements, but better procedures and techniques can reduce those uncertainties. Newtonian physics places no limits on how small the uncertainties can be. A Newtonian particle at any instant of time has an exact position x and an exact momentum p_x, and with sufficient care we can measure both x and p_x with such precision that the product $\Delta x \Delta p_x \rightarrow 0$. There are no inherent limits to our knowledge about a classical, or Newtonian, particle.

Heisenberg, however, made the bold and original statement that our knowledge has real limitations. No matter how clever you are, and no matter how good your experiment, you *cannot* measure both x and p_x simultaneously with arbitrarily good precision. Any measurements you make are limited by the condition that $\Delta x \Delta p_x \geq h/2$. **Our knowledge about a particle is *inherently* uncertain.**

Why? Because of the wave-like nature of matter. The "particle" is spread out in space, so there simply is not a precise value of its position x. Similarly, the de Broglie relationship between momentum and wavelength implies that we cannot know the momentum of a wave packet any more exactly than we can know its wavelength or frequency. Our belief that position and momentum have precise values is tied to our classical concept of a particle. As we revise our ideas of what atomic particles are like, we will also have to revise our old ideas about position and momentum.

EXAMPLE 40.5 The uncertainty of a dust particle

A 1.0-μm-diameter dust particle ($m \approx 10^{-15}$ kg) is confined within a 10-μm-long box. Can we know with certainty if the particle is at rest? If not, within what range is its velocity likely to be found?

MODEL All matter is subject to the Heisenberg uncertainty principle.

SOLVE If we know *for sure* that the particle is at rest, then $p_x = 0$ with no uncertainty. That is, $\Delta p_x = 0$. But then, according to the uncertainty principle, the uncertainty in our knowledge of the particle's position would have to be $\Delta x \rightarrow \infty$. In other words, we would have no knowledge at all about the particle's position—it could be anywhere! But that is not the case. We know the particle is *somewhere* in the box, so the uncertainty in our knowledge of its position is at most $\Delta x = L = 10\ \mu$m. With a finite Δx, the uncertainty Δp_x *cannot* be zero. We cannot know with certainty if the particle is at rest inside the box. No matter how hard we try to bring the particle to rest, the uncertainty in our knowledge of the particle's momentum will be $\Delta p_x \approx h/(2\Delta x) = h/2L$. We've assumed the most accurate measurements possible so that the $\geq$ in Heisenberg's uncertainty principle becomes $\approx$. Consequently, the range of possible velocities is

$$\Delta v_x = \frac{\Delta p_x}{m} \approx \frac{h}{2mL} \approx 3.0 \times 10^{-14}\ \text{m/s}$$

This range of possible velocities will be centered on $v_x = 0$ m/s if we have done our best to have the particle be at rest. Thus all we can know with certainty is that the particle's velocity is somewhere within the interval $-1.5 \times 10^{-14}\ \text{m/s} \leq v \leq 1.5 \times 10^{-14}\ \text{m/s}$.

ASSESS For practical purposes you might consider this to be a satisfactory definition of "at rest." After all, a particle moving with a speed of 1.5×10^{-14} m/s would need 6×10^{10} s to move a mere 1 mm. That is about 2000 years! Nonetheless, we can't know if the particle is "really" at rest.

EXAMPLE 40.6 The uncertainty of an electron

What range of velocities might an electron have if confined to a 0.10-nm-wide region, about the size of an atom?

MODEL Electrons are subject to the Heisenberg uncertainty principle.

SOLVE The analysis is the same as in Example 40.5. If we know that the electron's position is located within an interval $\Delta x \approx 0.1$ nm, then the best we can know is that its velocity is within the range

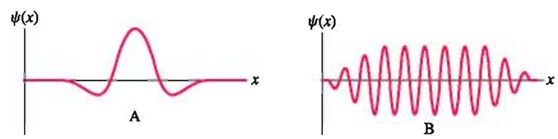
$$\Delta v_x = \frac{\Delta p_x}{m} \approx \frac{h}{2mL} \approx 4 \times 10^6 \text{ m/s}$$

Because the *average* velocity is zero, the best we can say is that the electron's velocity is somewhere in the interval -2×10^6 m/s $\leq v \leq 2 \times 10^6$ m/s. It is simply not possible to know the electron's velocity any more precisely than this.

ASSESS Unlike the situation in Example 40.5, where Δv was so small as to be of no practical consequence, our uncertainty about the electron's velocity is enormous—about 1% of the speed of light!

Once again, we see that even the smallest of macroscopic objects behaves very much like a classical Newtonian particle. Perhaps a 1-μm-diameter particle is slightly fuzzy and has a slightly uncertain velocity, but it is far beyond the measuring capabilities of even the very best instruments to detect this wave-like behavior. In contrast, the effects of the uncertainty principle at the atomic scale are stupendous. We are unable to determine the velocity of an electron in an atom-size container to any better accuracy than about 1% of the speed of light.

STOP TO THINK 40.6 Which of these particles, A or B, can you locate more precisely?



SUMMARY

The goal of Chapter 40 has been to introduce the wave-function description of matter and learn how it is interpreted.

General Principles

Wave Functions and the Probability Density

We cannot predict the exact trajectory of an atomic-level particle such as an electron. The best we can do is to predict the **probability** that a particle will be found in some region of space. The probability is determined by the particle's wave function $\psi(x)$.

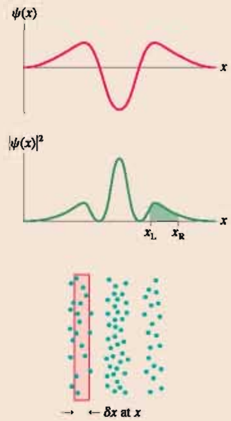
- $\psi(x)$ is a continuous, wave-like (i.e., oscillatory) function.
- The probability that a particle will be found in the narrow interval δx at position x is

$$\text{Prob(in } \delta x \text{ at } x) = |\psi(x)|^2\,\delta x$$

- $|\psi(x)|^2$ is the probability density $P(x)$.
- For the probability interpretation of $\psi(x)$ to make sense, the wave function must satisfy the normalization condition:
- $$\int_{-\infty}^{\infty} P(x)dx = \int_{-\infty}^{\infty} |\psi(x)|^2 dx = 1$$

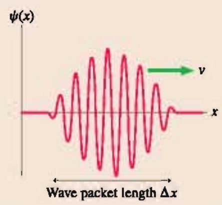
  That is, it is certain that the particle is *somewhere* on the x-axis.
- For an extended interval

$$\text{Prob}(x_L \le x \le x_R) = \int_{x_L}^{x_R} |\psi(x)|^2 dx = \text{area under the curve}$$



Heisenberg Uncertainty Principle

A particle with wave-like characteristics does not have a precise value of position x or a precise value of momentum p_x. Both are uncertain. The position uncertainty Δx and momentum uncertainty Δp_x are related by $\Delta x \Delta p_x \ge h/2$. The more you try to pin down the value of one, the less precisely the other can be known.

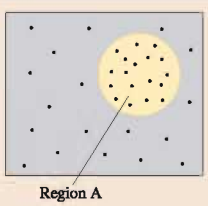


Important Concepts

The probability that a particle is found in region A is

$$P_A = \lim_{N_{tot}\to\infty} \frac{N_A}{N_{tot}}$$

If the probability is known, the expected number of A outcomes in N trials is $N_A = NP_A$.



A wave packet of duration Δt can be created by the superposition of many waves spanning the frequency range Δf. These are related by

$$\Delta f \Delta t \approx 1$$

CONCEPTUAL QUESTIONS

1. **FIGURE Q40.1** shows the probability density for photons to be detected on the x-axis.
   a. Is a photon more likely to be detected at $x = 0$ m or at $x = 1$ m? Explain.
   b. One million photons are detected. What is the expected number of photons in a 1-mm-wide interval at $x = 0.25$ m and at $x = 0.75$ m?

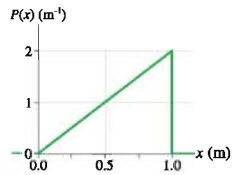

FIGURE Q40.1

2. What is the difference between the probability and the probability density?
3. For the electron wave function shown in **FIGURE Q40.3**, at what position or positions is the electron most likely to be found? Least likely to be found? Explain.

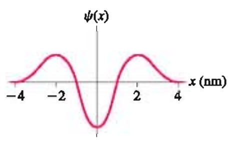

FIGURE Q40.3

4. **FIGURE Q40.4** shows the dot pattern of electrons landing on a screen.
   a. At what value or values of x is the electron probability density at maximum? Explain.
   b. Can you tell at what value or values of x the electron wave function $\psi(x)$ is most positive? If so, where? If not, why not?

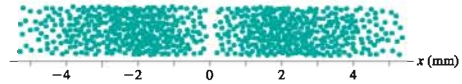

FIGURE Q40.4

5. What is the value of the constant a in **FIGURE Q40.5**?

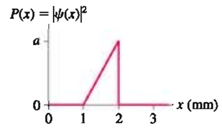

FIGURE Q40.5

6. **FIGURE Q40.6** shows wave packets for particles 1, 2, and 3. Which particle can have its velocity known most precisely? Explain.

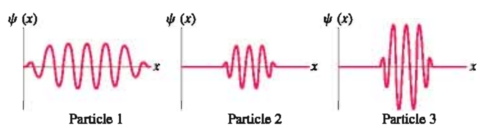

FIGURE Q40.6

EXERCISES AND PROBLEMS

Exercises

Section 40.1 Waves, Particles, and the Double-Slit Experiment

1. | An experiment has four possible outcomes, labeled A to D. The probability of A is $P_A = 40\%$ and of B is $P_B = 30\%$. Outcome C is twice as probable as outcome D. What are the probabilities P_C and P_D?
2. || Suppose you toss three coins into the air and let them fall on the floor. Each coin shows either a head or a tail.
   a. Make a table in which you list all the possible outcomes of this experiment. Call the coins A, B, and C.
   b. What is the probability of getting two heads and one tail? Explain.
   c. What is the probability of getting *at least* two heads?
3. | Suppose you draw a card from a regular deck of 52 cards.
   a. What is the probability that you draw an ace?
   b. What is the probability that you draw a spade?
4. | You are dealt 1 card each from 1000 decks of cards. What is the expected number of picture cards (jacks, queens, and kings)?
5. || Make a table in which you list all possible outcomes of rolling two dice. Call the dice A and B. What is the probability of rolling (a) a 7, (b) any double, and (c) a 6 or an 8? You can give the probabilities as fractions, such as 3/36.

Section 40.2 Connecting the Wave and Photon Views

6. | In one experiment, 2000 photons are detected in a 0.10-mm-wide strip where the amplitude of the electromagnetic wave is 10 V/m. How many photons are detected in a nearby 0.10-mm-wide strip where the amplitude is 30 V/m?
7. || In one experiment, 6000 photons are detected in a 0.10-mm-wide strip where the amplitude of the electromagnetic wave is 200 V/m. What is the wave amplitude at a nearby 0.20-mm-wide strip where 3000 photons are detected?
8. || 1.0×10^{10} photons pass through an experimental apparatus. How many of them land in a 0.10-mm-wide strip where the probability density is $20\ \text{m}^{-1}$?
9. | When 5×10^{12} photons pass through an experimental apparatus, 2.0×10^9 land in a 0.10-mm-wide strip. What is the probability density at this point?

Section 40.3 The Wave Function

10. | What are the units of ψ? Explain.
11. || FIGURE EX40.11 shows the probability density for an electron that has passed through an experimental apparatus. If 1.0×10^6 electrons are used, what is the expected number that will land in a 0.010-mm-wide strip at (a) $x = 0.000$ mm and (b) 2.000 mm?

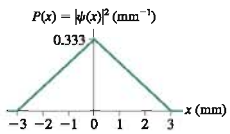

FIGURE EX40.11

12. || In an interference experiment with electrons, you find the most intense fringe is at $x = 7.0$ cm. There are slightly weaker fringes at $x = 6.0$ and 8.0 cm, still weaker fringes at $x = 4.0$ and 10.0 cm, and two very weak fringes at $x = 1.0$ and 13.0 cm. No electrons are detected at $x < 0$ cm or $x > 14$ cm.
    a. Sketch a graph of $|\psi(x)|^2$ for these electrons.
    b. Sketch a possible graph of $\psi(x)$.
    c. Are there other possible graphs for $\psi(x)$? If so, draw one.
13. | FIGURE EX40.13 shows the probability density for an electron that has passed through an experimental apparatus. What is the probability that the electron will land in a 0.010-mm-wide strip at (a) $x = 0.000$ mm, (b) $x = 0.500$ mm, (c) $x = 1.000$ mm, and (d) $x = 2.000$ mm?

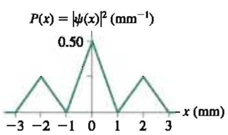

FIGURE EX40.13

Section 40.4 Normalization

14. || FIGURE EX40.14 is a graph of $|\psi(x)|^2$ for an electron.
    a. What is the value of a?
    b. Draw a graph of the wave function $\psi(x)$. (There is more than one acceptable answer.)
    c. What is the probability that the electron is located between $x = 1.0$ nm and $x = 2.0$ nm?

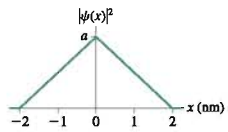

FIGURE EX40.14

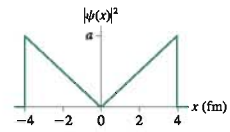

FIGURE EX40.15

15. || FIGURE EX40.15 is a graph of $|\psi(x)|^2$ for a neutron.
    a. What is the value of a?
    b. Draw a graph of the wave function $\psi(x)$. (There is more than one acceptable answer.)
    c. What is the probability that the neutron is located at a position with $|x| \geq 2$ fm?
16. || FIGURE EX40.16 shows the wave function of an electron.
    a. What is the value of c?
    b. Draw a graph of $|\psi(x)|^2$.
    c. What is the probability that the electron is located between $x = -1.0$ nm and $x = 1.0$ nm?

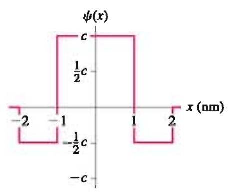

FIGURE EX40.16

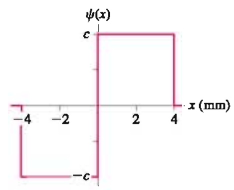

FIGURE EX40.17

17. || FIGURE EX40.17 shows the wave function of a neutron.
    a. What is the value of c?
    b. Draw a graph of $|\psi(x)|^2$.
    c. What is the probability that the neutron is located between $x = -1.0$ mm and $x = 1.0$ mm?

Section 40.5 Wave Packets

18. | What minimum bandwidth is needed to transmit a pulse that consists of 100 cycles of a 1.00 MHz oscillation?
19. || A radio-frequency amplifier is designed to amplify signals in the frequency range 80 MHz to 120 MHz. What is the shortest-duration radio-frequency pulse that can be amplified without distortion?
20. | Sound waves of 498 Hz and 502 Hz are superimposed at a temperature where the speed of sound in air is 340 m/s. What is the length Δx of one wave packet?
21. || A 1.5-μm-wavelength laser pulse is transmitted through a 2.0-GHz-bandwidth optical fiber. How many oscillations are in the shortest-duration laser pulse that can travel through the fiber?

Section 40.6 The Heisenberg Uncertainty Principle

22. || What is the position uncertainty, in nm, of an electron whose velocity is known to be between 3.48×10^5 m/s and 3.58×10^5 m/s?

23. || Andrea, whose mass is 50 kg, thinks she's sitting at rest in her 5.0-m-long dorm room as she does her physics homework. Can Andrea be sure she's at rest? If not, within what range is her velocity likely to be?

24. || A thin solid barrier in the xy-plane has a 10-μm-diameter circular hole. An electron traveling in the z-direction with $v_x = 0$ m/s passes through the hole. Afterward, is v_x still zero? If not, within what range is v_x likely to be?

25. || A proton is confined within an atomic nucleus of diameter 4.0 fm. Use a one-dimensional model to estimate the smallest range of speeds you might find for a proton in the nucleus.

Problems

26. | A 1.0-mm-diameter sphere bounces back and forth between two walls at $x = 0$ mm and $x = 100$ mm. The collisions are perfectly elastic, and the sphere repeats this motion over and over with no loss of speed. At a random instant of time, what is the probability that the center of the sphere is
    a. At exactly $x = 50.0$ mm?
    b. Between $x = 49.0$ mm and $x = 51.0$ mm?
    c. At $x \geq 75$ mm?

27. || A radar antenna broadcasts electromagnetic waves with a period of 0.100 ns. What range of frequencies would need to be superimposed to create a 1.0-ns-long radar pulse?

28. || Ultrasound pulses of with a frequency of 1.000 MHz are transmitted into water, where the speed of sound is 1500 m/s. The spatial length of each pulse is 12 mm.
    a. How many complete cycles are contained in one pulse?
    b. What range of frequencies must be superimposed to create each pulse?

29. || FIGURE P40.29 shows a *pulse train*. The period of the pulse train is $T = 2\Delta t$, where Δt is the duration of each pulse. What is the maximum pulse-transmission rate (pulses per second) through an electronics system with a 200 kHz bandwidth? (This is the bandwidth allotted to each FM radio station.)

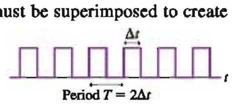

FIGURE P40.29

30. || Consider a single-slit diffraction experiment using electrons. (Single-slit diffraction was described in Section 22.4.) Using Figure 40.5 as a model, draw
    a. A dot picture showing the arrival positions of the first 40 or 50 electrons.
    b. A graph of $|\psi(x)|^2$ for the electrons on the detection screen.
    c. A graph of $\psi(x)$ for the electrons. Keep in mind that ψ, as a wave-like function, oscillates between positive and negative.

31. || An experiment finds electrons to be uniformly distributed over the interval $0\text{ cm} \leq x \leq 2$ cm, with no electrons falling outside this interval.
    a. Draw a graph of $|\psi(x)|^2$ for these electrons.
    b. What is the probability that an electron will land within the interval 0.79 to 0.81 cm?
    c. If 10^6 electrons are detected, how many will be detected in the interval 0.79 to 0.81 cm?
    d. What is the probability density at $x = 0.80$ cm?

32. || In an experiment with 10,000 electrons, which land symmetrically on both sides of $x = 0$, 5000 are detected in the range $-1.0\text{ cm} \leq x \leq +1.0$ cm, 7500 are detected in the range $-2.0\text{ cm} \leq x \leq +2.0$ cm, and all 10,000 are detected in the range $-3.0\text{ cm} \leq x \leq +3.0$ cm. Draw a graph of a probability density that is consistent with these data. (There may be more than one acceptable answer.)

33. || FIGURE P40.33 shows $|\psi(x)|^2$ for the electrons in an experiment.
    a. Is the electron wave function normalized? Explain.
    b. Draw a graph of $\psi(x)$ over this same interval. Provide a numerical scale on both axes. (There may be more than one acceptable answer.)
    c. What is the probability that an electron will be detected in a 0.0010-cm-wide region at $x = 0.00$ cm? At $x = 0.50$ cm? At $x = 0.999$ cm?
    d. If 10^4 electrons are detected, how many are expected to land in the interval $-0.30\text{ cm} \leq x \leq 0.30$ cm?

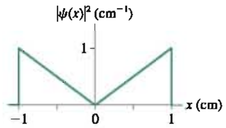

FIGURE P40.33

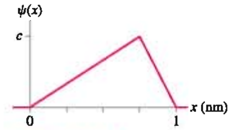

FIGURE P40.34

34. || FIGURE P40.34 shows the wave function of a particle confined between $x = 0$ nm and $x = 1.0$ nm. The wave function is zero outside this region.
    a. Determine the value of the constant c, as defined in the figure.
    b. Draw a graph of the probability density $P(x) = |\psi(x)|^2$.
    c. Draw a dot picture showing where the first 40 or 50 particles might be found.
    d. Calculate the probability of finding the particle in the interval $0.0\text{ nm} \leq x \leq 0.3$ nm.

35. || FIGURE P40.35 shows the wave function of a particle confined between $x = -4.0$ mm and $x = 4.0$ mm. The wave function is zero outside this region.
    a. Determine the value of the constant c, as defined in the figure.
    b. Draw a graph of the probability density $P(x) = |\psi(x)|^2$.
    c. Draw a dot picture showing where the first 40 or 50 particles might be found.
    d. Calculate the probability of finding the particle in the interval $-2.0\text{ mm} \leq x \leq 2.0$ mm.

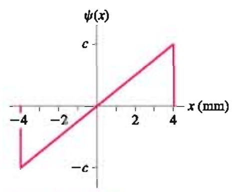

FIGURE P40.35

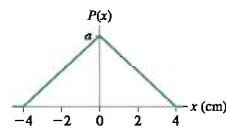

FIGURE P40.36

36. || FIGURE P40.36 shows the probability density for finding a particle at position x.
    a. Determine the value of the constant a, as defined in the figure.
    b. At what value of x are you most likely to find the particle? Explain.
    c. Within what range of positions centered on your answer to part b are you 75% certain of finding the particle?
    d. Interpret your answer to part c by drawing the probability density graph and shading the appropriate region.

37. ‖ An electron that is confined to $x \geq 0$ nm has the normalized wave function

$$\psi(x) = \begin{cases} 0 & x < 0 \text{ nm} \\ (1.414 \text{ nm}^{-1/2})e^{-x/(1.0 \text{ nm})} & x \geq 0 \text{ nm} \end{cases}$$

where x is in nm.

a. What is the probability of finding the electron in a 0.010-nm-wide region at $x = 1.0$ nm?
b. What is the probability of finding the electron in the interval $0.50 \text{ nm} \leq x \leq 1.50$ nm?

38. ‖ A particle is described by the wave function

$$\psi(x) = \begin{cases} ce^{x/L} & x \leq 0 \text{ mm} \\ ce^{-x/L} & x \geq 0 \text{ mm} \end{cases}$$

where $L = 2.0$ mm.

a. Sketch graphs of both the wave function and the probability density as functions of x.
b. Determine the normalization constant c.
c. Calculate the probability of finding the particle within 1.0 mm of the origin.
d. Interpret your answer to part b by shading the region representing this probability on the appropriate graph in part a.

39. ‖ Consider the electron wave function

$$\psi(x) = \begin{cases} c\sqrt{1 - x^2} & |x| \leq 1 \text{ cm} \\ 0 & |x| \geq 1 \text{ cm} \end{cases}$$

where x is in cm.

a. Determine the normalization constant c.
b. Draw a graph of $\psi(x)$ over the interval $-2 \text{ cm} \leq x \leq 2$ cm. Provide numerical scales on both axes.
c. Draw a graph of $|\psi(x)|^2$ over the interval $-2 \text{ cm} \leq x \leq 2$ cm. Provide numerical scales.
d. If 10^4 electrons are detected, how many will be in the interval $0.00 \text{ cm} \leq x \leq 0.50$ cm?

40. ‖ Consider the electron wave function

$$\psi(x) = \begin{cases} c\sin\left(\dfrac{2\pi x}{L}\right) & 0 \leq x \leq L \\ 0 & x < 0 \text{ or } x > L \end{cases}$$

a. Determine the normalization constant c. Your answer will be in terms of L.
b. Draw a graph of $\psi(x)$ over the interval $-L \leq x \leq 2L$.
c. Draw a graph of $|\psi(x)|^2$ over the interval $-L \leq x \leq 2L$.
d. What is the probability that an electron is in the interval $0 \leq x \leq L/3$?

41. ‖ The probability density for finding a particle at position x is

$$P(x) = \begin{cases} \dfrac{a}{(1 - x)} & -1 \text{ mm} \leq x < 0 \text{ mm} \\ b(1 - x) & 0 \text{ mm} \leq x \leq 1 \text{ mm} \end{cases}$$

and zero elsewhere.

a. You will learn in Chapter 41 that the wave function must be a *continuous* function. Assuming that to be the case, what can you conclude about the relationship between a and b?
b. Draw a graph of the probability density over the interval $-2 \text{ mm} \leq x \leq 2$ mm.
c. Determine values for a and b.
d. What is the probability that the particle will be found to the left of the origin?

42. ‖ A pulse of light is created by the superposition of many waves that span the frequency range $f_0 - \frac{1}{2}\Delta f \leq f \leq f_0 + \frac{1}{2}\Delta f$, where $f_0 = c/\lambda$ is called the *center frequency* of the pulse. Laser technology can generate a pulse of light that has a wavelength of 600 nm and lasts a mere 6.0 fs (1 fs = 1 femtosecond $= 10^{-15}$ s).

a. What is the center frequency of this pulse of light?
b. How many cycles, or oscillations, of the light wave are completed during the 6.0 fs pulse?
c. What range of frequencies must be superimposed to create this pulse?
d. What is the spatial length of the laser pulse as it travels through space?
e. Draw a snapshot graph of this wave packet.

43. ‖‖ What is the smallest one-dimensional box in which you can confine an electron if you want to know for certain that the electron's speed is no more than 10 m/s?

44. ‖ A small speck of dust with mass 1.0×10^{-13} g has fallen into the hole shown in FIGURE P40.44 and appears to be at rest. According to the uncertainty principle, could this particle have enough energy to get out of the hole? If not, what is the deepest hole of this width from which it would have a good chance to escape?

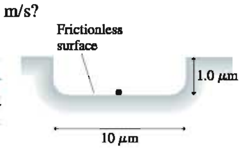

FIGURE P40.44

45. ‖ Physicists use laser beams to create an *atom trap* in which atoms are confined within a spherical region of space with a diameter of about 1 mm. The scientists have been able to cool the atoms in an atom trap to a temperature of approximately 1 nK, which is extremely close to absolute zero, but it would be interesting to know if this temperature is close to any limit set by quantum physics. We can explore this issue with a one-dimensional model of a sodium atom in a 1.0-mm-long box.

a. Estimate the *smallest* range of speeds you might find for a sodium atom in this box.
b. Even if we do our best to bring a group of sodium atoms to rest, individual atoms will have speeds within the range you found in part a. Because there's a distribution of speeds, suppose we estimate that the root-mean-square speed v_{rms} of the atoms in the trap is half the value you found in part a. Use this v_{rms} to estimate the temperature of the atoms when they've been cooled to the limit set by the uncertainty principle.

46. ‖ You learned in Chapter 38 that, except for hydrogen, the mass of a nucleus with atomic number Z is larger than the mass of the Z protons. The additional mass was ultimately discovered to be due to neutrons, but prior to the discovery of the neutron it was suggested that a nucleus with mass number A might contain A protons and $(A - Z)$ electrons. Such a nucleus would have the mass of A protons, but its net charge would be only Ze.

a. We know that the diameter of a nucleus is approximately 10 fm. Model the nucleus as a one-dimensional box and find the minimum range of speeds that an electron would have in such a box.
b. What does your answer imply about the possibility that the nucleus contains electrons? Explain.

47. ‖ a. Starting with the expression $\Delta f \Delta t \approx 1$ for a wave packet, find an expression for the product $\Delta E \Delta t$ for a photon.
b. Interpret your expression. What does it tell you?
c. The Bohr model of atomic quantization says that an atom in an excited state can jump to a lower-energy state by emitting a photon. The Bohr model says nothing about how long this process takes. You'll learn in Chapter 42 that the

time any particular atom spends in the excited state before emitting a photon is unpredictable, but the *average lifetime* Δt of many atoms can be determined. You can think of Δt as being the uncertainty in your knowledge of how long the atom spends in the excited state. A typical value is $\Delta t \approx 10$ ns. Consider an atom that emits a photon with a 500 nm wavelength as it jumps down from an excited state. What is the uncertainty in the energy of the photon? Give your answer in eV.

d. What is the *fractional uncertainty* $\Delta E/E$ in the photon's energy?

Challenge Problems

48. FIGURE CP40.48 shows 1.0-μm-diameter dust particles ($m = 1.0 \times 10^{-15}$ kg) in a vacuum chamber. The dust particles are released from rest above a 1.0-μm-diameter hole, fall through the hole (there's just barely room for the particles to go through), and land on a detector at distance d below.

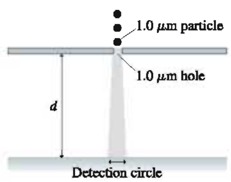

FIGURE CP40.48

a. If the particles were purely classical, they would all land in the same 1.0-μm-diameter circle. But quantum effects don't allow this. If $d = 1.0$ m, by how much does the diameter of the circle in which most dust particles land exceed 1.0 μm? Is this increase in diameter likely to be detectable?

b. Quantum effects would be noticeable if the detection-circle diameter increased by 10% to 1.1 μm. At what distance d would the detector need to be placed to observe this increase in the diameter?

49. The wave function of a particle is

$$\psi(x) = \sqrt{\frac{b}{\pi(x^2 + b^2)}}$$

where b is a positive constant. Find the probability that the particle is located in the interval $-b \le x \le b$.

50. The wave function of a particle is

$$\psi(x) = \begin{cases} \dfrac{b}{(1 + x^2)} & -1 \text{ mm} \le x < 0 \text{ mm} \\ c(1 + x)^2 & 0 \text{ mm} \le x \le 1 \text{ mm} \end{cases}$$

and zero elsewhere.

a. You will learn in Chapter 41 that the wave function must be a *continuous* function. Assuming that to be the case, what can you conclude about the relationship between b and c?

b. Draw graphs of the wave function and the probability density over the interval -2 mm $\le x \le 2$ mm.

c. What is the probability that the particle will be found to the right of the origin?

51. Consider the electron wave function

$$\psi(x) = \begin{cases} cx & |x| \le 1 \text{ nm} \\ \dfrac{c}{x} & |x| \ge 1 \text{ nm} \end{cases}$$

where x is in nm.

a. Determine the normalization constant c.

b. Draw a graph of $\psi(x)$ over the interval -5 nm $\le x \le 5$ nm. Provide numerical scales on both axes.

c. Draw a graph of $|\psi(x)|^2$ over the interval -5 nm $\le x \le 5$ nm. Provide numerical scales.

d. If 10^6 electrons are detected, how many will be in the interval -1.0 nm $\le x \le 1.0$ nm?

STOP TO THINK ANSWERS

Stop to Think 40.1: 10. The probability of a 1 is $P_1 = \frac{1}{6}$. Similarly, $P_6 = \frac{1}{6}$. The probability of a 1 *or* a 6 is $P_{1\,\text{or}\,6} = \frac{1}{6} + \frac{1}{6} = \frac{1}{3}$. Thus the expected number is $30(\frac{1}{3}) = 10$.

Stop to Think 40.2: A > B = D > C. $|A(x)|^2$ is proportional to the density of dots.

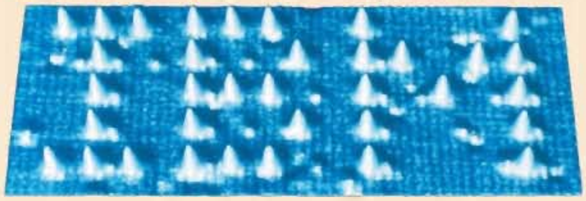
Stop to Think 40.3: x_C. The probability is largest at the point where the *square* of $\psi(x)$ is largest.

Stop to Think 40.4: b. The area $\frac{1}{2}a(2 \text{ mm})$ must equal 1.

Stop to Think 40.5: b. $\Delta t = 1.0 \times 10^{-7}$ s. The bandwidth is $\Delta f_B = 1/\Delta t = 1.0 \times 10^7$ Hz $= 10$ MHz.

Stop to Think 40.6: A. Wave packet A has a smaller spatial extent Δx. The wavelength isn't relevant.

41 One-Dimensional Quantum Mechanics



An example of atomic engineering. Thirty-five xenon atoms have been manipulated into position with the probe tip of a scanning tunneling microscope.

▶ Looking Ahead

The goal of Chapter 41 is to understand and apply the essential ideas of quantum mechanics. In this chapter you will learn to:

- Use a strategy for finding and interpreting wave functions.
- Draw wave functions with appropriate shapes.
- Use potential-energy functions to make quantum-mechanical models.
- Understand and use several important quantum-mechanical models.
- Calculate the probability of quantum-mechanical tunneling.

◀ Looking Back

Quantum mechanics will be developed around two fundamental ideas: energy diagrams and wave functions. A review of energy diagrams in Chapter 10 is especially important. Please review:

- Section 10.7 Energy diagrams.
- Sections 39.4 and 39.5 Matter waves and the Bohr model of quantization.
- Sections 40.3 and 40.4 Wave functions and normalization.

Quantum mechanics is not just for physicists any more. It is now an essential tool in the design of semiconductor devices such as diode lasers. Whole new classes of devices, called *quantum-well devices,* have been designed and built to exploit the quantization of energy levels. We will look at some examples in this chapter.

Also at the cutting edge of engineering science is the design and manufacture of *nanostructures*—small machines or other devices only a few hundred nanometers in size. Many scientists and engineers envision a day in the near future when nanostructures will be constructed literally atom by atom. Quantum effects will be important in devices this small. This photograph—of a structure built by scientists at IBM's research laboratory by moving xenon atoms around on a metal surface—shows an early example of "atomic engineering."

Our goal for this chapter is to introduce the essential ideas of quantum mechanics. Although the real world is three-dimensional, we will limit our study of quantum mechanics to one dimension. This will allow us to focus on the fundamental concepts of quantum physics without becoming overwhelmed by mathematical complications. We will discuss some of the aspects of finding and using wave functions, then look at several applications of quantum mechanics. We'll conclude this chapter with a look at a phenomenon called *quantum-mechanical tunneling,* one of the more startling aspects of quantum physics.

41.1 Schrödinger's Equation: The Law of Psi

In the winter of 1925, just before Christmas, the Austrian physicist Erwin Schrödinger gathered together a few books and headed off to a villa in the Swiss Alps. He had recently learned of de Broglie's 1924 suggestion that matter has wave-like properties, and he wanted some time free from distractions to think about it. Before the trip was over, Schrödinger had discovered the law of quantum mechanics.

Schrödinger's goal was to predict the outcome of atomic experiments, a goal that had eluded classical physics. The mathematical equation that he developed is now called the **Schrödinger equation.** It is the law of quantum mechanics in the same way that Newton's laws are the laws of classical mechanics. It would make sense to call it Schrödinger's law, but by tradition it is called simply the Schrödinger equation.

You learned in Chapter 40 that a matter particle is characterized in quantum physics by its wave function $\psi(x)$. If you know a particle's wave function, you can predict the probability of detecting it in some region of space. That's all well and good, but Chapter 40 didn't provide any method for determining wave functions. The Schrödinger equation is the missing piece of the puzzle. It is an equation for finding a particle's wave function $\psi(x)$ along the x-axis.

Consider an atomic particle with mass m and mechanical energy E whose interactions with the environment can be characterized by a one-dimensional potential-energy function $U(x)$. The Schrödinger equation for the particle's wave function is

$$\frac{d^2\psi}{dx^2} = -\frac{2m}{\hbar^2}[E - U(x)]\psi(x) \quad \text{(the Schrödinger equation)} \tag{41.1}$$

This is a differential equation whose solution is the wave function $\psi(x)$ that we seek. Our first goal is to learn what this equation means and how it is used.

Erwin Schrödinger.

Justifying the Schrödinger Equation

The Schrödinger equation can be neither derived nor proved. It is not an outgrowth of any previous theory. Its success depended on its ability to explain the various phenomena that had refused to yield to a classical-physics analysis and to make new predictions that were subsequently verified.

Although the Schrödinger equation cannot be derived, the reasoning behind it can at least be made *plausible*. De Broglie had postulated a wave-like nature for matter in which a particle of mass m, velocity v, and momentum $p = mv$ has a wavelength

$$\lambda = \frac{h}{p} = \frac{h}{mv} \tag{41.2}$$

Schrödinger's goal was to find a *wave equation* for which the solution would be a wave function having the de Broglie wavelength.

An oscillatory wave-like function with wavelength λ is

$$\psi(x) = \psi_0 \sin\left(\frac{2\pi x}{\lambda}\right) \tag{41.3}$$

where ψ_0 is the amplitude of the wave function. Suppose we take a second derivative of $\psi(x)$:

$$\frac{d^2\psi}{dx^2} = \frac{d}{dx}\frac{d\psi}{dx} = -\frac{(2\pi)^2}{\lambda^2}\psi_0 \sin\left(\frac{2\pi x}{\lambda}\right)$$

We can use the definition of $\psi(x)$, from Equation 41.3, to write the second derivative as

$$\frac{d^2\psi}{dx^2} = -\frac{(2\pi)^2}{\lambda^2}\psi(x) \tag{41.4}$$

Equation 41.4 relates the wavelength λ to a combination of the wave function $\psi(x)$ and its second derivative.

NOTE ► These manipulations are not specific to quantum mechanics. Equation 41.4, which is well known for classical waves, applies equally well to sound waves and waves on a string. ◄

Schrödinger's insight was to identify λ with the de Broglie wavelength of a particle. We can write the de Broglie wavelength in terms of the particle's kinetic energy K as

$$\lambda = \frac{h}{mv} = \frac{h}{\sqrt{2m(\frac{1}{2}mv^2)}} = \frac{h}{\sqrt{2mK}} \tag{41.5}$$

Notice that **the de Broglie wavelength increases as the particle's kinetic energy decreases.** This observation will play a key role.

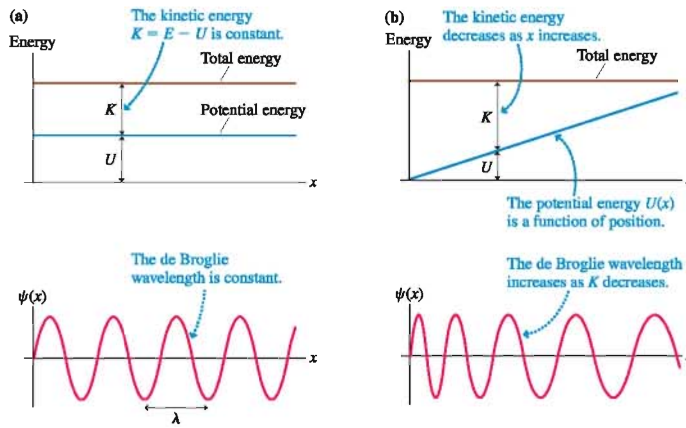
If we square this expression for λ and substitute it into Equation 41.4, we find

$$\frac{d^2\psi}{dx^2} = -\frac{(2\pi)^2 2mK}{h^2}\psi(x) = -\frac{2m}{\hbar^2}K\psi(x) \tag{41.6}$$

where $\hbar = h/2\pi$. Equation 41.6 is a differential equation for the function $\psi(x)$. The solution to this equation is the sinusoidal wave function of Equation 41.3, where λ is the de Broglie wavelength for a particle with kinetic energy K.

Our derivation of Equation 41.6 assumed that the particle's kinetic energy K is constant. The energy diagram of FIGURE 41.1a reminds you that a particle's kinetic energy remains constant as it moves along the x-axis only if its potential energy U is constant. In this case, the de Broglie wavelength is the same at all positions.

FIGURE 41.1 The de Broglie wavelength changes as a particle's kinetic energy changes.



In contrast, FIGURE 41.1b shows the energy diagram for a particle whose kinetic energy is *not* constant. This particle speeds up or slows down as it moves along the x-axis, transforming potential energy to kinetic energy or vice versa. Consequently, its de Broglie wavelength changes with position.

Suppose a particle's potential energy—gravitational or electric or any other kind of potential energy—is described by the function $U(x)$ or $U(y)$. That is, the potential energy is a *function of position* along the axis of motion. For example, the gravitational potential energy near the earth's surface is the function $U(y) = mgy$.

If E is the particle's total mechanical energy, its kinetic energy at position x is

$$K = E - U(x) \tag{41.7}$$

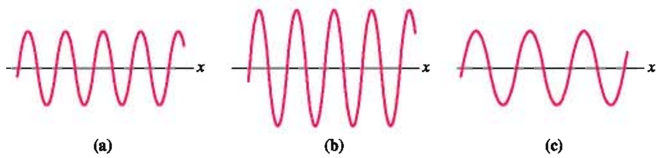
If we use this expression for K in Equation 41.6, that equation becomes

$$\frac{d^2\psi}{dx^2} = -\frac{2m}{\hbar^2}[E - U(x)]\psi(x)$$

This is Equation 41.1, the Schrödinger equation for the particle's wave function $\psi(x)$.

NOTE ▶ This has not been a derivation of the Schrödinger equation. We've made a *plausibility argument,* based on de Broglie's hypothesis about matter waves, but only experimental evidence will show if this equation has merit. ◀

STOP TO THINK 41.1 Three de Broglie waves are shown for particles of equal mass. Rank in order, from fastest to slowest, the speeds of particles a, b, and c.



Quantum-Mechanical Models

Long ago, in your study of Newtonian mechanics, you learned the importance of *models.* To understand the motion of an object, we made simplifying assumptions: that the object could be represented by a particle, that friction could be described in a simple way, that air resistance could be neglected, and so on. Models allowed us to understand the primary features of an object's motion without getting lost in the details.

The same holds true in quantum mechanics. The exact description of a microscopic atom or a solid is extremely complicated. Our only hope for using quantum mechanics effectively is to make a number of simplifying assumptions—that is, to make a **quantum-mechanical model** of the situation. Much of this chapter will be about building and using quantum-mechanical models.

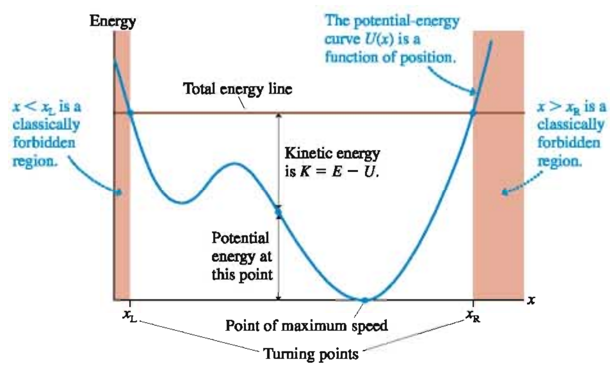
The test of a model's success is its agreement with experimental measurement. Laboratory experiments cannot measure $\psi(x)$, and they rarely make direct measurements of probabilities. Thus it will be important to tie our models to measurable quantities such as wavelengths, charges, currents, times, and temperatures.

There's one very important difference between models in classical mechanics and quantum mechanics. Classical models are described in terms of *forces,* and Newton's laws are a connection between force and motion. The Schrödinger equation for the wave function is written in terms of *energies.* Consequently, quantum-mechanical modeling involves finding a potential-energy function $U(x)$ that describes a particle's interactions with its environment.

FIGURE 41.2 reminds you how to interpret an energy diagram. We will use energy diagrams extensively in this and the remaining chapters to portray quantum-mechanical models. A review of Section 10.7, where energy diagrams were introduced, is highly recommended.

ActivPhysics ONLINE 20.1

FIGURE 41.2 Interpreting an energy diagram.



41.2 Solving the Schrödinger Equation

The Schrödinger equation is a second-order differential equation, meaning that it is a differential equation for $\psi(x)$ involving its second derivative. However, this textbook does not assume that you know how to solve differential equations. As we did with Newton's laws, we will restrict ourselves to situations where the mathematical skills are those you have been developing in calculus.

The solution to an algebraic equation is simply a number. For example, $x = 3$ is the solution to the equation $2x = 6$. In contrast, the solution to a differential equation is a *function*. You saw this idea in the preceding section, where Equation 41.6 was constructed so that the function $\psi(x) = \psi_0\sin(2\pi x/\lambda)$ was a solution.

The Schrödinger equation can't be solved until the potential-energy function $U(x)$ has been specified. Different potential-energy functions result in different wave functions, just as different forces lead to different trajectories in classical mechanics. Once $U(x)$ has been specified, the solution of the differential equation is a *function* $\psi(x)$. We will usually display the solution as a graph of $\psi(x)$ versus x.

Restrictions and Boundary Conditions

Not all functions $\psi(x)$ make *acceptable* solutions to the Schrödinger equation. That is, some functions may satisfy the Schrödinger equation but not be physically meaningful. We have previously encountered restrictions in our solutions of algebraic equations. We insist, for physical reasons, that masses be positive rather than negative numbers, that positions be real rather than imaginary numbers, and so on. Mathematical solutions not meeting these restrictions are rejected as being unphysical.

Because we want to interpret $|\psi(x)|^2$ as a probability density, we have to insist that the function $\psi(x)$ be one for which this interpretation is possible. The conditions or restrictions on acceptable solutions are called the **boundary conditions.** You will see, in later examples, how the boundary conditions help us choose the correct solution for $\psi(x)$. The primary conditions the wave function must obey are:

1. $\psi(x)$ is a continuous function.
2. $\psi(x) = 0$ if x is in a region where it is physically impossible for the particle to be.
3. $\psi(x) \to 0$ as $x \to +\infty$ and $x \to -\infty$.
4. $\psi(x)$ is a normalized function.

The last is not, strictly speaking, a boundary condition but is an auxiliary condition we require for the wave function to have a useful interpretation. Boundary condition 3 is needed to enable the normalization integral $\int|\psi(x)|^2dx$ to converge.

Once boundary conditions have been established, there are general approaches to solving the Schrödinger equation: Use general techniques for solving second-order differential equations, solve the equation numerically on a computer, or guess.

More advanced courses make extensive use of the first and second approaches. However, we are not assuming a knowledge of differential equations, so you will not be asked to use these methods. The third, although it sounds almost like cheating, is widely used in simple situations where we can use physical arguments to infer the functional form of the wave function. The upcoming examples will illustrate this third approach.

A quadratic algebraic equation has two different solutions. Similarly, a second-order differential equation has two independent solutions $\psi_1(x)$ and $\psi_2(x)$. By "independent solutions" we mean that $\psi_2(x)$ is not just a constant multiple of $\psi_1(x)$, such as $3\psi_1(x)$, but that $\psi_1(x)$ and $\psi_2(x)$ are totally different functions.

Suppose that $\psi_1(x)$ and $\psi_2(x)$ are known to be two independent solutions of the Schrödinger equation. A theorem you will learn in differential equations states that a *general solution* of the equation can be written as

$$\psi(x) = A\psi_1(x) + B\psi_2(x) \tag{41.8}$$

where A and B are constants whose values are determined by the boundary conditions. Equation 41.8 is a powerful statement, although one that will make more sense after

you see it applied in upcoming examples. The main point is that **if we can find two independent solutions $\psi_1(x)$ and $\psi_2(x)$ by guessing, then Equation 41.8 is the general solution to the Schrödinger equation.**

Quantization

We've asserted that the Schrödinger equation is the law of quantum mechanics, but thus far we've not said anything about quantization. Although the particle's total energy E appears in the Schrödinger equation, it is treated in the equation as an unspecified constant. However, it will turn out that there are *no* acceptable solutions for most values of E. That is, there are no functions $\psi(x)$ that satisfy both the Schrödinger equation *and* the boundary conditions. Acceptable solutions exist only for *discrete* values of E. The energies for which solutions exist are the quantized energies of the system. Thus, as you'll see, the Schrödinger equation has quantization as a built-in feature.

Problem Solving in Quantum Mechanics

Our problem-solving strategy for classical mechanics focused on identifying and using forces. In quantum mechanics we're interested in *energy* rather than forces. The critical step in solving a problem in quantum mechanics is to determine the particle's potential-energy function $U(x)$. Identifying the interactions that cause a potential energy is the *physics* of the problem. Once the potential-energy function is known, it is "just mathematics" to solve for the wave function.

PROBLEM-SOLVING STRATEGY 41.1 Quantum-mechanics problems

MP

MODEL Determine a potential-energy function that describes the particle's interactions. Make simplifying assumptions.

VISUALIZE The potential-energy curve is the pictorial representation.

- Draw the potential-energy curve.
- Identify known information.
- Establish the boundary conditions that the wave function must satisfy.

SOLVE The Schrödinger equation is the mathematical representation.

- Utilize the boundary conditions.
- Normalize the wave functions.
- Draw graphs of $\psi(x)$ and $|\psi(x)|^2$.
- Determine the allowed energy levels.
- Calculate probabilities, wavelengths, or other specific quantities.

ASSESS Check that your result has the correct units, is reasonable, and answers the question.

The solutions to the Schrödinger equation are the stationary states of the system. Bohr had postulated the existence of stationary states, but he didn't know how to find them. Now we have a strategy for finding them.

Bohr's idea of transitions, or quantum jumps, between stationary states remains very important in Schrödinger's quantum mechanics. The system can jump from one stationary state, characterized by wave function $\psi_i(x)$ and energy E_i, to another state, characterized by $\psi_f(x)$ and E_f, by emitting or absorbing a photon of frequency

$$f = \frac{\Delta E}{h} = \frac{|E_f - E_i|}{h}$$

Thus the solutions to the Schrödinger equation will allow us to predict the emission and absorption spectra of a quantum system. These predictions will test the validity of Schrödinger's theory.

41.3 A Particle in a Rigid Box: Energies and Wave Functions

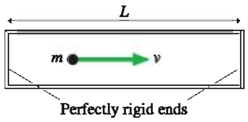


FIGURE 41.3 A particle in a rigid box of length L.

FIGURE 41.3 shows a particle of mass m confined in a rigid, one-dimensional box of length L. The walls of the box are assumed to be perfectly rigid, and the particle undergoes perfectly elastic reflections from the ends. This situation is known as a "particle in a box."

A classical particle bounces back and forth between the walls of the box. There are no restrictions on the speed or kinetic energy of a classical particle. In contrast, a wave-like particle characterized by a de Broglie wavelength sets up a standing wave as it reflects back and forth. In Chapters 25 and 39, we found that a standing de Broglie wave automatically leads to energy quantization. That is, only certain discrete energies are allowed. However, our hypothesis of a de Broglie standing wave was just a guess, with no real justification, because we had no theory about how a wave-like particle ought to behave.

We will now revisit this problem from the new perspective of quantum mechanics. The basic questions we want to answer in this, and any quantum-mechanics problem, are:

20.2 ActivPhysics ONLINE

- What are the allowed energies of the particle?
- What is the wave function associated with each energy?
- In which part of the box is the particle most likely to be found?

We can use Problem-Solving Strategy 41.1 to answer these questions.

Model: Identify a Potential-Energy Function

By a *rigid box* we mean a box whose walls are so sturdy that they can confine a particle no matter how fast the particle moves. Furthermore, the walls are so stiff that they do not flex or give as the particle bounces. No real container has these attributes, so the rigid box is a *model* of a situation in which a particle is extremely well confined. Our first task is to characterize the rigid box in terms of a potential-energy function.

Let's establish a coordinate axis with the boundaries of the box at $x = 0$ and $x = L$. The rigid box has three important characteristics:

1. The particle can move freely between 0 and L at constant speed and thus with constant kinetic energy.
2. No matter how much kinetic energy the particle has, its turning points are at $x = 0$ and $x = L$.
3. The regions $x < 0$ and $x > L$ are forbidden. The particle cannot leave the box.

A potential-energy function that describes the particle in this situation is

$$U_{\text{rigid box}}(x) = \begin{cases} 0 & 0 \le x \le L \\ \infty & x < 0 \quad \text{or} \quad x > L \end{cases} \tag{41.9}$$

Inside the box, the particle has only kinetic energy. The infinitely high potential-energy barriers prevent the particle from ever having $x < 0$ or $x > L$ no matter how much kinetic energy it may have. It is this potential energy for which we want to solve the Schrödinger equation.

Visualize: Establish Boundary Conditions

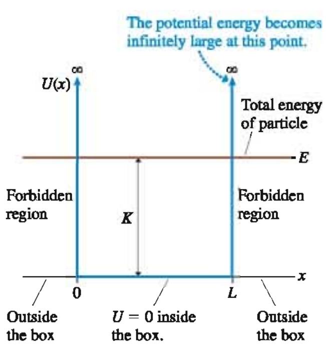

FIGURE 41.4 The energy diagram of a particle in a rigid box of length L.

FIGURE 41.4 is the energy diagram of a particle in the rigid box. You can see that $U = 0$ and $E = K$ inside the box. The upward arrows labeled ∞ indicate that the potential energy becomes infinitely large at the walls of the box ($x = 0$ and $x = L$).

NOTE ▶ Figure 41.4 is not a picture of the box. It is a graphical representation of the particle's kinetic and potential energy. ◀

Next, we need to establish the boundary conditions that the solution must satisfy. Because it is physically impossible for the particle to be outside the box, we require

$$\psi(x) = 0 \quad \text{for } x < 0 \quad \text{or} \quad x > L \tag{41.10}$$

That is, there is zero probability of finding the particle outside the box.

Furthermore, the wave function must be a *continuous* function. That is, there can be no break in the wave function at any point. Because the solution is zero everywhere outside the box, continuity requires that the wave function inside the box obey the two conditions

$$\psi(\text{at } x = 0) = 0 \quad \text{and} \quad \psi(\text{at } x = L) = 0 \tag{41.11}$$

In other words, as FIGURE 41.5 shows, the oscillating wave function inside the box must go to zero at the boundaries to be continuous with the wave function outside the box. This requirement of the wave function is equivalent to saying that a standing wave on a string must have a node at the ends.

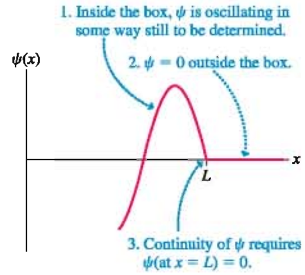

FIGURE 41.5 Applying boundary conditions to the wave function of a particle in a box.

Solve I: Find the Wave Functions

At all points *inside* the box the potential energy is $U(x) = 0$. Thus the Schrödinger equation inside the box is

$$\frac{d^2\psi}{dx^2} = -\frac{2mE}{\hbar^2}\psi(x) \tag{41.12}$$

There are two aspects to solving this equation:

1. For what values of E does Equation 41.12 have physically meaningful solutions?
2. What are the solutions $\psi(x)$ for those values of E?

To begin, let's simplify the notation by defining $\beta^2 = 2mE/\hbar^2$. Equation 41.12 is then

$$\frac{d^2\psi}{dx^2} = -\beta^2\psi(x) \tag{41.13}$$

We're going to solve this differential equation by guessing! Can you think of any functions whose second derivative is a *negative* constant times the function itself? Two such functions are

$$\psi_1(x) = \sin\beta x \quad \text{and} \quad \psi_2(x) = \cos\beta x \tag{41.14}$$

Both are solutions to Equation 41.13 because

$$\frac{d^2\psi_1}{dx^2} = \frac{d^2}{dx^2}(\sin\beta x) = -\beta^2\sin\beta x = -\beta^2\psi_1(x)$$
$$\frac{d^2\psi_2}{dx^2} = \frac{d^2}{dx^2}(\cos\beta x) = -\beta^2\cos\beta x = -\beta^2\psi_2(x)$$

Furthermore, these are *independent* solutions because $\psi_2(x)$ is not a multiple or a rearrangement of $\psi_1(x)$. Consequently, according to Equation 41.8, the general solution to the Schrödinger equation for the particle in a rigid box is

$$\psi(x) = A\sin\beta x + B\cos\beta x \tag{41.15}$$

where

$$\beta = \frac{\sqrt{2mE}}{\hbar} \tag{41.16}$$

The constants A and B must be determined by using the boundary conditions of Equation 41.11. First, the wave function must go to zero at $x = 0$. That is,

$$\psi(\text{at } x = 0) = A \cdot 0 + B \cdot 1 = 0 \tag{41.17}$$

This boundary condition can be satisfied only if $B = 0$. The $\cos\beta x$ term may satisfy the differential equation in a mathematical sense, but it is not a physically meaningful solution for this problem because it does not satisfy the boundary conditions. Thus the physically meaningful solution is

$$\psi(x) = A\sin\beta x$$

The wave function must also go to zero at $x = L$. That is,

$$\psi(\text{at } x = L) = A\sin\beta L = 0 \tag{41.18}$$

This condition could be satisfied by $A = 0$, but then we wouldn't have a wave function at all! Fortunately, that isn't necessary. This boundary condition is also satisfied if $\sin\beta L = 0$, which requires

$$\beta L = n\pi \quad \text{or} \quad \beta = \frac{n\pi}{L} \qquad n = 1, 2, 3, \ldots \tag{41.19}$$

Notice that n starts with 1, not 0. The value $n = 0$ would give $\beta = 0$ and make $\psi = 0$ at all points, a physically meaningless solution.

Thus the solutions to the Schrödinger equation for a particle in a rigid box are

$$\psi_n(x) = A\sin\beta_n x = A\sin\left(\frac{n\pi x}{L}\right) \qquad n = 1, 2, 3, \ldots \tag{41.20}$$

We've found a whole *family* of solutions, each corresponding to a different value of the integer n. These wave functions represent the stationary states of the particle in the box. The constant A remains to be determined.

Solve II: Find the Allowed Energies

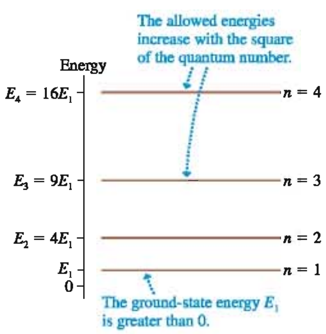
Equation 41.16 defined β. Equation 41.19 then placed restrictions on the possible values of β:

$$\beta_n = \frac{\sqrt{2mE_n}}{\hbar} = \frac{n\pi}{L} \qquad n = 1, 2, 3, \ldots \tag{41.21}$$

where the value of β and the energy associated with the integer n have been labeled β_n and E_n. We can solve for E_n by squaring both sides:

$$E_n = n^2\frac{\pi^2\hbar^2}{2mL^2} = n^2\frac{h^2}{8mL^2} \qquad n = 1, 2, 3, \ldots \tag{41.22}$$

FIGURE 41.6 The energy-level diagram for a particle in a box.



where, in the last step, we used the definition $\hbar = h/2\pi$. For a particle in a box, **these energies are the only values of E for which there are physically meaningful solutions to the Schrödinger equation.**

We have found that the particle's energy is quantized! It is useful to write the energies of the stationary states as

$$E_n = n^2E_1 \tag{41.23}$$

where E_n is the energy of the stationary state with *quantum number n*. The smallest possible energy $E_1 = h^2/8mL^2$ is the energy of the $n = 1$ *ground state*. These allowed energies are shown in the *energy-level diagram* of FIGURE 41.6. Recall, from Chapter 39, that an energy-level diagram is not a graph (the horizontal axis doesn't represent anything) but a "ladder" of allowed energies.

Equation 41.22 is identical to the energies we found in Chapter 39 by requiring the de Broglie wave of a particle in a box to form a standing wave. Only now we have a theory that tells not only the energies but also the wave functions.

EXAMPLE 41.1 An electron in a box

An electron is confined to a rigid box. What is the length of the box if the energy difference between the first and second states is 3.0 eV?

MODEL Model the electron as a particle in a rigid one-dimensional box of length L.

SOLVE The first two quantum states, with $n = 1$ and $n = 2$, have energies E_1 and $E_2 = 4E_1$. Thus the energy difference between the states is

$$\Delta E = 3E_1 = \frac{3h^2}{8mL^2} = 3.0\text{ eV} = 4.8 \times 10^{-19}\text{ J}$$

The length of the box for which $\Delta E = 3.0$ eV is

$$L = \sqrt{\frac{3h^2}{8m\Delta E}} = 6.14 \times 10^{-10}\text{ m} = 0.614\text{ nm}$$

ASSESS The expression for E_1 is in SI units, so energies must be in J, not eV.

Solve III: Normalize the Wave Functions

We can determine the constant A by requiring the wave functions to be normalized. The normalization condition, which we found in Chapter 40, is

$$\int_{-\infty}^{\infty} |\psi(x)|^2 dx = 1$$

This is the mathematical statement that the particle must be *somewhere* on the x-axis. The integration limits extend to $\pm\infty$, but here we need to integrate only from 0 to L because the wave function is zero outside the box. Thus

$$\int_0^L |\psi_n(x)|^2 dx = A_n^2 \int_0^L \sin^2\left(\frac{n\pi x}{L}\right) dx = 1 \qquad (41.24)$$

or

$$A_n = \left[\int_0^L \sin^2\left(\frac{n\pi x}{L}\right) dx\right]^{-1/2} \qquad (41.25)$$

We placed a subscript n on A_n because it is possible that the normalization constant is different for each wave function in the family. This is a standard integral. We will leave it as a homework problem for you to show that its value, for any n, is

$$A_n = \sqrt{\frac{2}{L}} \qquad n = 1, 2, 3, \ldots \qquad (41.26)$$

We now have a complete solution to the problem. The normalized wave function for the particle in quantum state n is

$$\psi_n(x) = \begin{cases} \sqrt{\dfrac{2}{L}} \sin\left(\dfrac{n\pi x}{L}\right) & 0 \le x \le L \\ 0 & x < 0 \text{ and } x > L \end{cases} \qquad (41.27)$$

41.4 A Particle in a Rigid Box: Interpreting the Solution

Our solution to the quantum-mechanical problem of a particle in a box tells us that:

1. The particle must have energy $E_n = n^2 E_1$, where $n = 1, 2, 3, \ldots$ is the quantum number. $E_1 = h^2/8mL^2$ is the energy of the $n = 1$ ground state.
2. The wave function for a particle in quantum state n is

$$\psi_n(x) = \begin{cases} \sqrt{\dfrac{2}{L}} \sin\left(\dfrac{n\pi x}{L}\right) & 0 \le x \le L \\ 0 & x < 0 \text{ and } x > L \end{cases}$$

These are the stationary states of the system.

3. The probability density for finding the particle at position x inside the box is

$$P_n(x) = |\psi_n(x)|^2 = \frac{2}{L}\sin^2\!\left(\frac{n\pi x}{L}\right) \tag{41.28}$$

FIGURE 41.7 Wave functions and probability densities for a particle in a rigid box of length L.

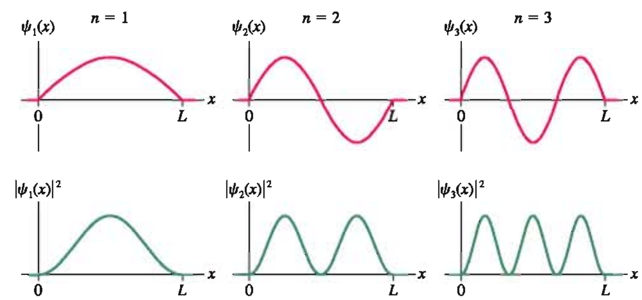


FIGURE 41.8 An alternative way to show the potential-energy diagram, the energies, and the wave functions.

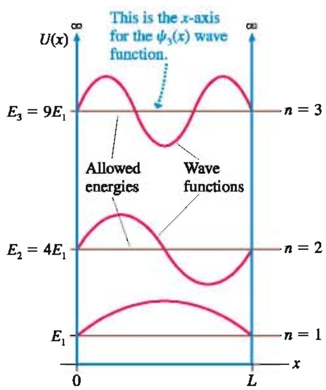


A graphical presentation will make these results more meaningful. **FIGURE 41.7** shows the wave functions $\psi(x)$ and the probability densities $P(x) = |\psi(x)|^2$ for quantum states $n = 1$ to 3. Notice that the wave functions go to zero at the boundaries and thus are continuous with $\psi = 0$ outside the box.

The wave functions $\psi(x)$ for a particle in a rigid box are analogous to standing waves on a string that is tied at both ends. You can see that **$\psi_n(x)$ has $(n - 1)$ nodes (zeros), excluding the ends, and n antinodes (maxima and minima).** This is a general result for any wave function, not just for a particle in a rigid box.

FIGURE 41.8 shows another way in which energies and wave functions are shown graphically in quantum mechanics. First, the graph shows the potential-energy function $U(x)$ of the particle. Second, the allowed energies are shown as horizontal lines (total energy lines) across the potential-energy graph. These are labeled with the quantum number n and the energy E_n. Third—and this is a bit tricky—the wave function for each n is drawn *as if* the energy line were the zero of the y-axis. That is, the graph of $\psi_n(x)$ is drawn on top of the E_n energy line. This allows energies and wave functions to be displayed simultaneously, but it does *not* imply that ψ_2 is in any sense "above" ψ_1. Both oscillate sinusoidally about zero, as Figure 41.7 shows.

EXAMPLE 41.2 Energy levels and quantum jumps

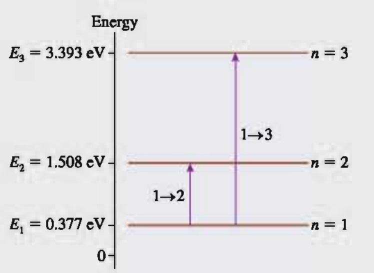
A semiconductor device known as a *quantum-well device* is designed to "trap" electrons in a 1.0-nm-wide region. Treat this as a one-dimensional problem.

a. What are the energies of the first three quantum states?
b. What wavelengths of light can these electrons absorb?

MODEL Model an electron in a quantum-well device as a particle confined in a rigid box of length $L = 1.0$ nm.

VISUALIZE **FIGURE 41.9** shows the first three energy levels and the transitions by which an electron in the ground state can absorb a photon.

FIGURE 41.9 Energy levels and quantum jumps for an electron in a quantum-well device.



SOLVE a. The particle's mass is $m = m_e = 9.11 \times 10^{-31}$ kg. The allowed energies, in both J and eV, are

$$E_1 = \frac{h^2}{8mL^2} = 6.03 \times 10^{-20}\ \text{J} = 0.377\ \text{eV}$$

$$E_2 = 4E_1 = 1.508\ \text{eV}$$

$$E_3 = 9E_1 = 3.393\ \text{eV}$$

b. An electron spends most of its time in the $n = 1$ ground state. According to Bohr's model of stationary states, the electron can absorb a photon of light and undergo a transition, or quantum jump, to $n = 2$ or $n = 3$ if the light has frequency $f = \Delta E/h$. The wavelengths, given by $\lambda = c/f = hc/\Delta E$, are

$$\lambda_{1\to 2} = \frac{hc}{E_2 - E_1} = 1098\ \text{nm}$$

$$\lambda_{1\to 3} = \frac{hc}{E_3 - E_1} = 411\ \text{nm}$$

ASSESS In practice, various complications usually make the $1 \to 3$ transition unobservable. But quantum-well devices do indeed exhibit strong absorption and emission at the $\lambda_{1\to 2}$ wavelength. In this example, which is typical of quantum-well devices, the wavelength is in the near-infrared portion of the spectrum. Devices such as these are used to construct the semiconductor lasers used in CD players and laser printers.

NOTE ▶ The wavelengths of light emitted or absorbed by a quantum system are determined by the *difference* between two allowed energies. Quantum jumps involve two stationary states. ◀

Zero-Point Motion

The lowest energy state in Example 41.2, the ground state, has $E_1 = 0.38$ eV. There is no stationary state having $E = 0$. Unlike a classical particle, **a quantum particle in a box cannot be at rest!** No matter how much its energy is reduced, such as by cooling it toward absolute zero, it cannot have energy less than E_1.

The particle motion associated with energy E_1, called the **zero-point motion,** is a consequence of Heisenberg's uncertainty principle. Because the particle is somewhere in the box, its position uncertainty is $\Delta x = L$. If the particle were at rest in the box, we would know that its velocity and momentum are exactly zero with *no* uncertainty: $\Delta p_x = 0$. But then $\Delta x \Delta p_x = 0$ would violate the Heisenberg uncertainty principle. One of the conclusions that follows from the uncertainty principle is that **a confined particle cannot be at rest.**

Although the particle's position and velocity are uncertain, the particle's energy in each state can be calculated with a high degree of precision. This distinction between a precise energy and uncertain position and velocity seems strange, but it is just our old friend the standing wave. In order to *have* a stationary state at all, the de Broglie waves have to form standing waves. Only for very precise frequencies, and thus precise energies, can the standing-wave pattern appear.

EXAMPLE 41.3 Nuclear energies

Protons and neutrons are tightly bound within the nucleus of an atom. If we use a one-dimensional model of a nucleus, what are the first three energy levels of a neutron in a 10-fm-diameter nucleus (1 fm $= 10^{-15}$ m)?

MODEL Model the nucleus as a one-dimensional box of length $L = 10$ fm. The neutron is confined within the box.

SOLVE The energy levels, with $L = 10$ fm and $m = m_n = 1.67 \times 10^{-27}$ kg, are

$$E_1 = \frac{h^2}{8mL^2} = 3.29 \times 10^{-13}\ \text{J} = 2.06\ \text{MeV}$$

$$E_2 = 4E_1 = 8.24\ \text{MeV}$$

$$E_3 = 9E_1 = 18.54\ \text{MeV}$$

ASSESS An electron confined in an atom-size space has energies of a few eV. A neutron confined in a nucleus-size space has energies of a few *million* eV.

EXAMPLE 41.4 The probabilities of locating the particle

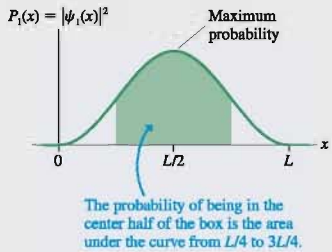
A particle in a rigid box of length L is in its ground state.

a. Where is the particle most likely to be found?
b. What are the probabilities of finding the particle in an interval of width $0.01L$ at $x = 0.00L$, $0.25L$, and $0.50L$?
c. What is the probability of finding the particle in the center half of the box?

MODEL The wave functions for a particle in a rigid box have been determined.

VISUALIZE FIGURE 41.10 shows the probability density $P_1(x) = |\psi_1(x)|^2$ in the ground state.

FIGURE 41.10 Probability density for a particle in the ground state.



SOLVE a. The particle is most likely to be found at the point where the probability density $P(x)$ is a maximum. You can see from Figure 41.10 that the point of maximum probability for $n = 1$ is $x = L/2$.

b. For a *small* width δx, the probability of finding the particle in δx at position x is

$$\text{Prob(in } \delta x \text{ at } x) = P_1(x)\delta x = |\psi_1(x)|^2 \delta x = \frac{2}{L}\sin^2\left(\frac{\pi x}{L}\right)\delta x$$

The interval $\delta x = 0.01L$ is sufficiently small for this to be valid. The probabilities of finding the particle are

$$\text{Prob(in } 0.01L \text{ at } x = 0.00L) = 0.000 = 0.0\%$$

$$\text{Prob(in } 0.01L \text{ at } x = 0.25L) = 0.010 = 1.0\%$$

$$\text{Prob(in } 0.01L \text{ at } x = 0.50L) = 0.020 = 2.0\%$$

c. The center half of the box stretches from $x = L/4$ to $x = 3L/4$. The probability that the particle is in this interval is the area under the probability-density curve:

$$\text{Prob}\left(\text{in interval } \frac{1}{4}L \text{ to } \frac{3}{4}L\right) = \int_{L/4}^{3L/4} P_1(x)\,dx$$

$$= \frac{2}{L}\int_{L/4}^{3L/4} \sin^2\left(\frac{\pi x}{L}\right)dx$$

$$= \left[\frac{x}{L} - \frac{1}{\pi}\sin\left(\frac{\pi x}{L}\right)\cos\left(\frac{\pi x}{L}\right)\right]_{L/4}^{3L/4}$$

$$= \frac{1}{2} + \frac{1}{\pi} = 0.818$$

ASSESS If a particle in a box is in the $n = 1$ ground state, there is an 81.8% chance of finding it in the center half of the box. The probability is greater than 50% because, as you can see in Figure 41.10, the probability density $P_1(x)$ is larger near the center of the box than near the boundaries.

This has been a lengthy presentation of the particle-in-a-box problem. However, it was important that we explore the method of solution completely. Future examples will now go more quickly because many of the issues discussed here will not need to be repeated.

STOP TO THINK 41.2 A particle in a rigid box in the $n = 2$ stationary state is most likely to be found

a. In the center of the box.
b. One-third of the way from either end.
c. One-quarter of the way from either end.
d. It is equally likely to be found at any point in the box.

41.5 The Correspondence Principle

Suppose we confine an electron in a microscopic box, then allow the box to get bigger and bigger. What started out as a quantum-mechanical situation should, when the box becomes macroscopic, eventually look like a classical-physics situation. Similarly, a classical situation such as two charged particles revolving about each other should begin to exhibit quantum behavior as the orbit size becomes smaller and smaller.

These examples suggest that there should be some in-between size, or energy, for which the quantum-mechanical solution corresponds in some way to the solution of classical mechanics. Niels Bohr put forward the idea that the *average* behavior of a quantum system should begin to look like the classical solution in the limit that the quantum number becomes very large—that is, as $n \to \infty$. Because the radius of the Bohr hydrogen atom is $r = n^2 a_B$, the atom becomes a macroscopic object as n becomes very large. Bohr's idea, that the quantum world should blend smoothly into the classical world for high quantum numbers, is today known as the **correspondence principle.**

Our quantum knowledge of a particle in a box is given by its probability density

$$P_{\text{quant}}(x) = |\psi_n(x)|^2 = \frac{2}{L}\sin^2\left(\frac{n\pi x}{L}\right) \qquad (41.29)$$

To what classical quantity can the probability density be compared as $n \to \infty$?

Interestingly, we can also define a classical probability density $P_{\text{class}}(x)$. A classical particle follows a well-defined trajectory, but suppose we observe the particle at random times. For example, suppose the box containing a classical particle has a viewing window. The window is normally closed, but at random times, selected by a random-number generator, the window opens for a brief interval δt and you can measure the particle's position. When the window opens, what is the probability that the particle will be in a narrow interval δx at position x?

The probability of finding a classical particle within a small interval δx is equal to the *fraction of its time* that it spends passing through δx. That is, you're more likely to find the particle in those intervals δx where it spends lots of time, less likely to find it in a δx where it spends very little time.

If the particle oscillates between two turning points with period T, the time it spends moving from one turning point to the other is $\frac{1}{2}T$. As it moves between the turning points, it passes once through the interval δx at position x, taking time δt to do so. Consequently, the probability of finding the particle within this interval is

$$\text{Prob}_{\text{class}}(\text{in } \delta x \text{ at } x) = \text{fraction of time spent in } \delta x = \frac{\delta t}{\frac{1}{2}T} \qquad (41.30)$$

The amount of time needed to pass through δx is $\delta t = \delta x / v(x)$, where $v(x)$ is the particle's velocity at position x. Thus the probability of finding the particle in the interval δx at position x is

$$\text{Prob}_{\text{class}}(\text{in } \delta x \text{ at } x) = \frac{\delta x / v(x)}{\frac{1}{2}T} = \frac{2}{Tv(x)}\delta x \qquad (41.31)$$

You learned in Chapter 40 that the probability is related to the probability density by

$$\text{Prob}_{\text{class}}(\text{in } \delta x \text{ at } x) = P_{\text{class}}(x)\,\delta x$$

Thus the classical probability density for finding a particle at position x is

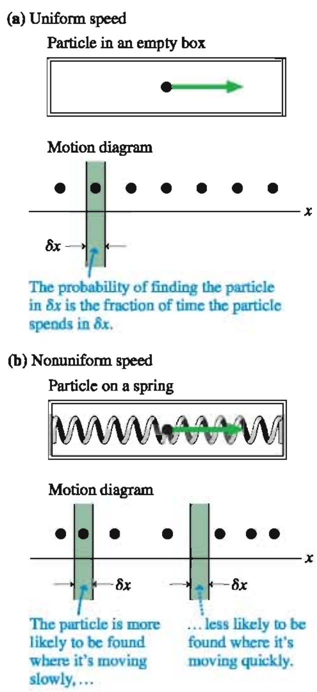
$$P_{\text{class}}(x) = \frac{2}{Tv(x)} \qquad (41.32)$$

where the velocity $v(x)$ is expressed as a function of x. **Classically, a particle is more likely to be found where it is moving slowly, less likely to be found where it is moving quickly.**

NOTE ▶ Our derivation of Equation 41.32 made no assumptions about the particle's motion other than the requirement that it be periodic. This is the classical probability density for any oscillatory motion. ◀

FIGURE 41.11a shows a motion diagram of a classical particle in a rigid box of length L. The particle's speed is a *constant* $v(x) = v_0$ as it bounces back and forth between

FIGURE 41.11 The classical probability density is indicated by the density of dots in a motion diagram.



the walls. The particle travels distance $2L$ during one round trip, so the period is $T = 2L/v_0$. Consequently, the classical probability density for a particle in a box is

$$P_{\text{class}}(x) = \frac{2}{(2L/v_0)v_0} = \frac{1}{L} \tag{41.33}$$

$P_{\text{class}}(x)$ is independent of x, telling us that the particle is equally likely to be found *anywhere* in the box.

In contrast, FIGURE 41.11b shows a particle with nonuniform speed. A mass on a spring slows down near the turning points, so it spends more time near the ends of the box than in the middle. Consequently the classical probability density for this particle is a maximum at the edges and a minimum at the center. We'll look at this classical probability density again later in the chapter.

EXAMPLE 41.5 The classical probability of locating the particle

A classical particle is in a rigid 10-cm-long box. What is the probability that, at a random instant of time, the particle is in a 1.0-mm-wide interval at the center of the box?

SOLVE The particle's probability density is

$$P_{\text{class}}(x) = \frac{1}{L} = \frac{1}{10\text{ cm}} = 0.10\text{ cm}^{-1}$$

The probability that the particle is in an interval of width $\delta x = 1.0\text{ mm} = 0.10\text{ cm}$ is

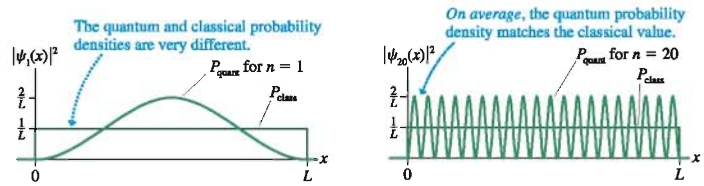
$$\begin{aligned}\text{Prob(in } \delta x \text{ at } x = 5\text{ cm)} &= P(x)\delta x = (0.10\text{ cm}^{-1})(0.10\text{ cm}) \\ &= 0.010 = 1.0\%\end{aligned}$$

ASSESS The classical probability is 1.0% because 1.0 mm is 1% of the 10 cm length.

FIGURE 41.12 shows the quantum and the classical probability densities for the $n = 1$ and $n = 20$ quantum states of a particle in a rigid box. Notice that:

- The quantum probability density oscillates between a minimum of 0 and a maximum of $2/L$, so it oscillates around the classical probability density $1/L$.
- For $n = 1$, the quantum and classical probability densities are quite different. The ground state of the quantum system will be very nonclassical.
- For $n = 20$, *on average* the quantum particle's behavior looks very much like that of the classical particle.

FIGURE 41.12 The quantum and classical probability densities for a particle in a box.



As n gets even bigger and the number of oscillations increases, the probability of finding the particle in an interval δx will be the same for both the quantum and the classical particles as long as δx is large enough to include several oscillations of the wave function. As Bohr predicted, the quantum-mechanical solution "corresponds" to the classical solution in the limit $n \to \infty$.

41.6 Finite Potential Wells

Figure 41.4, the potential-energy diagram for a particle in a rigid box, is an example of a **potential well**, so named because the graph of the potential-energy "hole" looks like a well from which you might draw water. The rigid box was an *infinite* potential well. There was no chance that a particle inside could escape the infinitely high walls.

No box is infinitely strong. A more realistic model of a confined particle is the *finite* potential well shown in FIGURE 41.13a. A particle with total energy $E < U_0$ is confined within the well, bouncing back and forth between turning points at $x = 0$ and $x = L$. The regions $x < 0$ and $x > L$ are **classically forbidden regions** for a particle with $E < U_0$. However, the particle will escape the well if it somehow manages to acquire energy $E > U_0$.

Recall that the zero of energy is arbitrary. Figure 41.13a defined $U = 0$ as the potential energy inside the well. FIGURE 41.13b has repositioned the zero of energy at the level of the "energy plateau" on both sides of the well. **Figures 41.13a and 41.13b are the same potential well.** Both have width L and depth U_0, and both have the same wave functions and the same allowed energies (relative to our choice of $E = 0$). Which we use is a matter of convenience.

We've made no mention of the *force* that is responsible for this potential well. An electron confined within a semiconductor by an electric force has a potential energy that can be modeled as a finite potential well. So does a proton confined within the nucleus by the nuclear force. The Schrödinger equation depends on the *shape* of the potential-energy function, not the cause. Hence *any* situation in which a particle is confined can be modeled as a finite potential well.

Although it is possible to solve the Schrödinger equation exactly for the finite potential well, the result is cumbersome and not especially illuminating. Instead, we'll present the results of numerical calculations. The derivation of the wave functions and energy levels is not as important as understanding and interpreting the results.

As a first example, consider an electron in a 2.0-nm-wide potential well of depth $U_0 = 1.0$ eV. These are reasonable parameters for an electron in a semiconductor device. FIGURE 41.14a is a graphical presentation of the allowed energies and wave functions. For comparison, FIGURE 41.14b shows the first three energy levels and wave functions for a rigid box ($U_0 \to \infty$) with the same 2.0 nm width.

FIGURE 41.13 A finite potential well of width L and depth U_0.

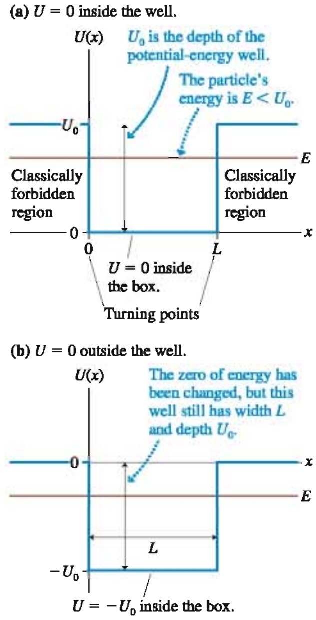


FIGURE 41.14 Energy levels and wave functions for a finite potential well. For comparison, the energies and wave functions are shown for a rigid box of equal width.

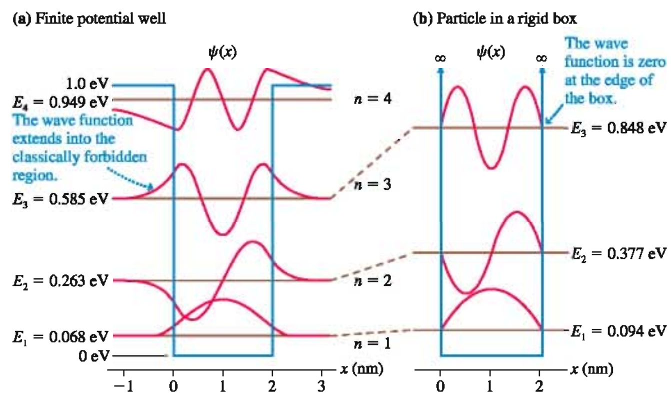


The quantum-mechanical solution for a particle in a finite potential well has some important properties:

ActivPhysics ONLINE 20.3

- The particle's energy is quantized. A particle in the potential well *must* be in one of the stationary states with quantum numbers $n = 1, 2, 3, \ldots$.
- There are only a finite number of **bound states**—four in this example, although the number will be different in other examples. These wave functions represent electrons confined to, or bound in, the potential well. There are no stationary states with $E > U_0$ because such a particle would not remain in the well.

- The wave functions are qualitatively similar to those of a particle in a rigid box, but the energies are somewhat lower. This is because the wave functions are slightly more spread out. A slightly longer de Broglie wavelength corresponds to a lower velocity and thus a lower energy.
- Most interesting, perhaps, is that the wave functions of Figure 41.14a extend into the classically forbidden regions. It is as though a tennis ball penetrated partly *through* the racket's strings before bouncing back, but without breaking the strings.

EXAMPLE 41.6 Absorption spectrum of an electron

What wavelengths of light are absorbed by a semiconductor device in which electrons are confined in a 2.0-nm-wide region with a potential-energy depth of 1.0 eV?

MODEL The electron is in the finite potential well whose energies and wave functions were shown in Figure 41.14a.

SOLVE Photons can be absorbed if their energy $E_{photon} = hf$ exactly matches the energy difference ΔE between two energy levels. Because most electrons are in the $n = 1$ ground state, the absorption transitions are $1 \rightarrow 2$, $1 \rightarrow 3$, and $1 \rightarrow 4$.

The absorption wavelengths $\lambda = c/f$ are

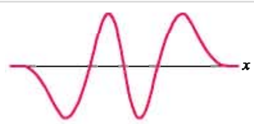
$$\lambda_{n\rightarrow m} = \frac{hc}{\Delta E} = \frac{hc}{|E_n - E_m|}$$

For this example, we find

$$\begin{aligned} \Delta E_{1-2} &= 0.195\text{ eV} & \lambda_{1\rightarrow 2} &= 6.37\ \mu\text{m} \\ \Delta E_{1-3} &= 0.517\text{ eV} & \lambda_{1\rightarrow 3} &= 2.40\ \mu\text{m} \\ \Delta E_{1-4} &= 0.881\text{ eV} & \lambda_{1\rightarrow 4} &= 1.41\ \mu\text{m} \end{aligned}$$

ASSESS These transitions are all infrared wavelengths.

STOP TO THINK 41.3 This is a wave function for a particle in a finite quantum well. What is the particle's quantum number?



The Classically Forbidden Region

The extension of a particle's wave functions into the classically forbidden region is an important difference between classical and quantum physics. Let's take a closer look at the wave function in the region $x \geq L$ of Figure 41.13a. The potential energy in the classically forbidden region is U_0; thus the Schrödinger equation for $x \geq L$ is

$$\frac{d^2\psi}{dx^2} = -\frac{2m}{\hbar^2}(E - U_0)\psi(x)$$

We're assuming a confined particle, with E less than U_0, so $E - U_0$ is negative. It will be useful to reverse the order of these and write

$$\frac{d^2\psi}{dx^2} = \frac{2m}{\hbar^2}(U_0 - E)\psi(x) = \frac{1}{\eta^2}\psi(x) \tag{41.34}$$

where

$$\eta^2 = \frac{\hbar^2}{2m(U_0 - E)} \tag{41.35}$$

is a *positive* constant. As a homework problem, you can show that the units of η are meters.

The Schrödinger equation of Equation 41.34 is one we can solve by guessing. We simply need to think of two functions whose second derivatives are a positive constant times the functions themselves. Two such functions, as you can quickly confirm, are $e^{x/\eta}$ and $e^{-x/\eta}$. Thus, according to Equation 41.8, the general solution of the Schrödinger equation for $x \geq L$ is

$$\psi(x) = Ae^{x/\eta} + Be^{-x/\eta} \quad \text{for } x \geq L \tag{41.36}$$

One requirement of the wave function is that $\psi \to 0$ as $x \to \infty$. The function $e^{x/\eta}$ diverges as $x \to \infty$, so the only way to satisfy this requirement is to set $A = 0$. Thus

$$\psi(x) = Be^{-x/\eta} \quad \text{for } x \geq L \tag{41.37}$$

This is an exponentially decaying function. Notice that all the wave functions in Figure 41.14a look like exponential decays for $x > L$.

The wave function must also be continuous. Suppose the oscillating wave function within the potential well ($x \leq L$) has the value ψ_{edge} when it reaches the classical boundary at $x = L$. To be continuous, the wave function of Equation 41.37 has to match this value at $x = L$. That is,

$$\psi(\text{at } x = L) = Be^{-L/\eta} = \psi_{edge} \tag{41.38}$$

This boundary condition at $x = L$ is sufficient to determine that the constant B is

$$B = \psi_{edge}e^{L/\eta} \tag{41.39}$$

If we use the Equation 41.39 result for B in Equation 41.37, we find that the wave function in the classically forbidden region of a finite potential well is

$$\psi(x) = \psi_{edge}e^{-(x-L)/\eta} \quad \text{for } x \geq L \tag{41.40}$$

In other words, **the wave function oscillates until it reaches the classical turning point at $x = L$, then it decays exponentially within the classically forbidden region.** A similar analysis could be done for $x \leq 0$.

FIGURE 41.15 shows the wave function in the classically forbidden region. You can see that the wave function at $x = L + \eta$ has decreased to

$$\psi(\text{at } x = L + \eta) = e^{-1}\psi_{edge} = 0.37\psi_{edge}$$

Although an exponential decay does not have a sharp ending point, the parameter η measures "about how far" the wave function extends past the classical turning point before the probability of finding the particle has decreased nearly to zero. This distance is called the **penetration distance:**

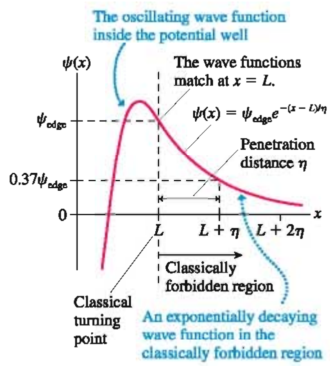
$$\text{penetration distance } \eta = \frac{\hbar}{\sqrt{2m(U_0 - E)}} \tag{41.41}$$

A classical particle reverses direction at the $x = L$ turning point. But atomic particles are not classical. Because of wave–particle duality, an atomic particle is "fuzzy" with no well-defined edge. Thus an atomic particle can spread a distance of roughly η into the classically forbidden region.

The penetration distance is unimaginably small for any macroscopic mass, but it can be significant for atomic particles. Notice that the penetration distance depends inversely on the quantity $U_0 - E$, the distance of the energy level below the top of the potential well. You can see in Figure 41.14a that η is much larger for the $n = 4$ state, near the top of the potential well, than for the $n = 1$ state.

NOTE ▶ In making use of Equation 41.41, you *must* use SI units of J s for $\hbar$ and J for the energies. The penetration distance η is then in meters. ◀

FIGURE 41.15 The wave function in the classically forbidden region.



EXAMPLE 41.7 Penetration distance of an electron

An electron is confined in a 2.0-nm-wide region with a potential-energy depth of 1.00 eV. What are the penetration distances into the classically forbidden region for an electron in the $n = 1$ and $n = 4$ states?

MODEL The electron is in the finite potential well whose energies and wave functions were shown in Figure 41.14a.

SOLVE The ground state has $U_0 - E_1 = 1.000 \text{ eV} - 0.068 \text{ eV} = 0.932 \text{ eV}$. Similarly, $U_0 - E_4 = 0.051$ eV in the $n = 4$ state. We can use Equation 41.41 to calculate

$$\eta = \frac{\hbar}{\sqrt{2m(U_0 - E)}} = \begin{cases} 0.20 \text{ nm} & n = 1 \\ 0.86 \text{ nm} & n = 4 \end{cases}$$

ASSESS These values are consistent with Figure 41.14a.

Quantum-Well Devices

In Part VI we developed a model of electrical conductivity in which the valence electrons of a metal form a loosely bound "sea of electrons." The typical speed of an electron is the rms speed:

$$v_{rms} = \sqrt{\frac{3k_B T}{m}}$$

where k_B is Boltzmann's constant. Hence at room temperature, where $v_{rms} \approx 1 \times 10^5$ m/s, the de Broglie wavelength of a typical conduction electron is

$$\lambda \approx \frac{h}{mv_{rms}} \approx 6 \text{ nm}$$

There is a range of wavelengths because the electrons have a range of speeds, but this is a typical value.

You've now seen many times that wave effects are significant only when the sizes of physical structures are comparable to or smaller than the wavelength. This is why the interference and diffraction of light are hard to observe and why the wave-like nature of matter becomes important only on microscopic scales. Because the de Broglie wavelength of conduction electrons is only a few nm, quantum effects are insignificant in electronic devices whose features are larger than about 100 nm. The electrons in macroscopic devices can be treated as classical particles, which is how we analyzed electric current in Chapter 31.

However, devices smaller than about 100 nm do exhibit quantum effects. Some semiconductor devices, such as the semiconductor lasers used in fiber-optic communications, now incorporate features only a few nm in size. Quantum effects play an important role in these devices.

FIGURE 41.16 A semiconductor diode laser with a single quantum well.

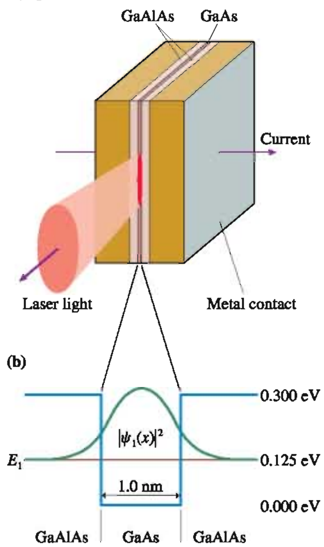


FIGURE 41.16a shows the construction of a *semiconductor diode laser.* Although the operating principles of diodes are beyond the scope of this textbook, we can note that a current travels through this device from left to right. In the center is a very thin layer of the semiconductor gallium arsenide (GaAs). It is surrounded on either side by layers of gallium aluminum arsenide (GaAlAs), and these in turn are embedded within the larger structure of the diode. The electrons within the central GaAs layer begin to emit laser light when the current through the diode exceeds some *threshold current.*

You can learn in a solid-state physics or materials engineering course that the electric potential energy of an electron is slightly lower in GaAs than in GaAlAs. This makes the GaAs layer a potential well for electrons, with higher-potential-energy GaAlAs "walls" on either side. As a result, the electrons become trapped within the thin GaAs layer. Such a device is called a **quantum-well laser.**

As an example, FIGURE 41.16b shows a quantum-well device with a 1.0-nm-thick GaAs layer in which the electron's potential energy is 0.300 eV lower than in the surrounding GaAlAs layers. A numerical solution of the Schrödinger equation finds that this potential well has only a *single* quantum state, $n = 1$ with $E_1 = 0.125$ eV. Every electron trapped in this quantum well has the *same* energy—a very nonclassical result! The fact that the electron energies are so well defined, in contrast to the range of electron energies in bulk material, is what makes this a useful device. You can also see from the probability density $|\psi|^2$ that the electrons are more likely to be found in the center of the layer than at the edges. This concentration of electrons makes it easier for the device to begin laser action.

Nuclear Physics

The nucleus of an atom consists of an incredibly dense assembly of protons and neutrons. The positively charged protons exert extremely strong electric repulsive forces on each other, so you might wonder how the nucleus keeps from exploding. During the 1930s, physicists found that protons and neutrons also exert an *attractive* force on each other. This force, one of the fundamental forces of nature, is called the *strong force.* It is the force that holds the nucleus together.

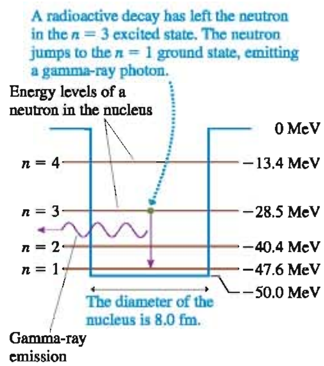
The primary characteristic of the strong force, other than its strength, is that it is a *short-range* force. The attractive strong force between two *nucleons* (a nucleon is either a proton or a neutron; the strong force does not distinguish between them) rapidly decreases to zero if they are separated by more than about 2 fm. This is in sharp contrast to the long-range nature of the electric force.

A reasonable model of the nucleus is to think of the protons and neutrons as particles in a nuclear potential well that is created by the strong force. The diameter of the potential well is equal to the diameter of the nucleus (this varies with atomic mass), and nuclear physics experiments have found that the depth of the potential well is ≈ 50 MeV.

The real potential well is three-dimensional, but let's make a simplified model of the nucleus as a one-dimensional potential well. FIGURE 41.17 shows the potential energy of a neutron along an x-axis passing through the center of the nucleus. Notice that the zero of energy has been chosen such that a "free" neutron, one outside the nucleus, has $E = 0$. Thus the potential energy inside the nucleus is -50 MeV. The 8.0 fm diameter shown is appropriate for a nucleus having atomic mass number $A \approx 40$, such as argon or potassium. Lighter nuclei will be a little smaller, heavier nuclei somewhat larger. (The potential-energy diagram for a proton is similar, but is complicated a bit by the electric potential energy.)

A numerical solution of the Schrödinger equation finds the four stationary states shown in Figure 41.17. The wave functions have been omitted, but they look essentially identical to the wave functions in Figure 41.14a. The major point to note is that the allowed energies differ by several *million* electron volts! These are enormous energies compared to those of an electron in an atom or a semiconductor. But recall that the energies of a particle in a rigid box, $E_n = n^2h^2/8mL^2$, are proportional to $1/L^2$. Our previous examples, with nanometer-size boxes, found energies in the eV range. When the box size is reduced to femtometers, the energies jump up into the MeV range.

FIGURE 41.17 There are four allowed energy levels for a neutron in this nuclear potential well.



It often happens that the nuclear decay of a radioactive atom leaves a neutron in an excited state. For example, Figure 41.17 shows a neutron that has been left in the $n = 3$ state by a previous radioactive decay. This neutron can now undergo a quantum jump to the $n = 1$ ground state by emitting a photon with energy

$$E_{\text{photon}} = E_3 - E_1 = 19.1 \text{ MeV}$$

and wavelength

$$\lambda_{\text{photon}} = \frac{c}{f} = \frac{hc}{E_{\text{photon}}} = 6.50 \times 10^{-5} \text{ nm}$$

This photon is $\approx 10^7$ times more energetic, and its wavelength $\approx 10^7$ times smaller, than the photons of visible light! These extremely high-energy photons are called **gamma rays.** Gamma-ray emission is, indeed, one of the primary processes in the decay of radioactive elements.

Our one-dimensional model cannot be expected to give accurate results for the energy levels or gamma-ray energies of any specific nucleus. Nonetheless, this model does provide a reasonable understanding of the energy-level structure in nuclei and correctly predicts that nuclei can emit photons having energies of several million electron volts. This model, when extended to three dimensions, becomes the basis for the *shell model* of the nucleus in which the protons and neutrons are grouped in various shells analogous to the electron shells around an atom that you remember from chemistry. You can learn more about nuclear physics and the shell model in Chapter 43.

41.7 Wave-Function Shapes

Bound-state wave functions are standing de Broglie waves. In addition to boundary conditions, two other factors govern the shapes of wave functions:

1. The de Broglie wavelength is inversely dependent on the particle's speed. Consequently, the node spacing is smaller (shorter wavelength) where the kinetic

energy is larger, and the spacing is larger (longer wavelength) where the kinetic energy is smaller.

2. A classical particle is more likely to be found where it is moving more slowly. In quantum mechanics, the probability of finding the particle increases as the wave-function amplitude increases. Consequently, the wave-function amplitude is larger where the kinetic energy is smaller, and it is smaller where the kinetic energy is larger.

We can use this information to draw reasonably accurate wave functions for the different allowed energies in a potential-energy well.

TACTICS BOX 41.1 Drawing wave functions (MP)

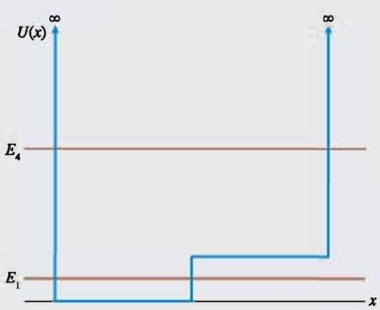
1. Draw a graph of the potential energy $U(x)$. Show the allowed energy E as a horizontal line. Locate the classical turning points.
2. Draw the wave function as a continuous, oscillatory function between the turning points. The wave function for quantum state n has n anti-nodes and $(n - 1)$ nodes (excluding the ends).
3. Make the wavelength longer (larger node spacing) and the amplitude higher in regions where the kinetic energy is smaller. Make the wavelength shorter and the amplitude lower in regions where the kinetic energy is larger.
4. Bring the wave function to zero at the edge of an infinitely high potential-energy "wall."
5. Let the wave function decay exponentially inside a classically forbidden region where $E < U$. The penetration distance η increases as E gets closer to the top of the potential-energy well.

Exercises 10–13

EXAMPLE 41.8 Sketching wave functions

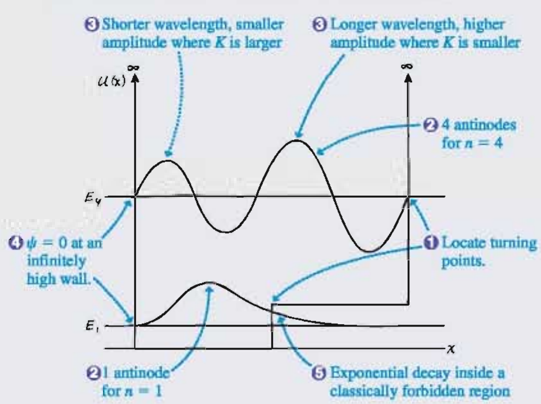
FIGURE 41.18 shows a potential-energy well and the allowed energies for the $n = 1$ and $n = 4$ quantum states. Sketch the $n = 1$ and $n = 4$ wave functions.

FIGURE 41.18 A potential-energy well.

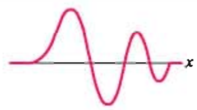


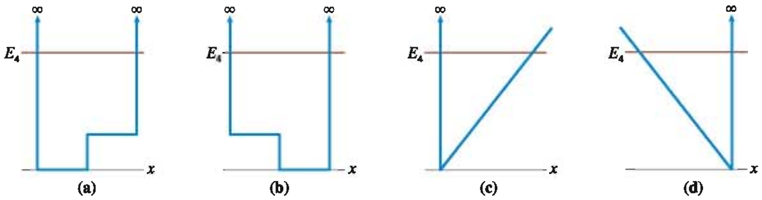
VISUALIZE The steps of Tactics Box 41.1 have been followed to sketch the wave functions shown in FIGURE 41.19.

FIGURE 41.19 The $n = 1$ and $n = 4$ wave functions.



STOP TO THINK 41.4 For which potential energy is this an appropriate $n = 4$ wave function?





41.8 The Quantum Harmonic Oscillator

Simple harmonic motion is exceptionally important in classical physics, where it serves as a prototype for more complex oscillations. As you might expect, a microscopic oscillator—the **quantum harmonic oscillator**—is equally important as a model of oscillations at the atomic level.

The defining characteristic of simple harmonic motion is a linear restoring force: $F = -kx$, where k is the spring constant. The corresponding potential-energy function, as you learned in Chapter 10, is

$$U(x) = \frac{1}{2}kx^2 \tag{41.42}$$

where we'll assume that the equilibrium position is $x_e = 0$. The potential energy of a harmonic oscillator is shown in FIGURE 41.20. It is a potential-energy well with curved sides.

A classical particle of mass m oscillates with angular frequency

$$\omega = \sqrt{\frac{k}{m}} \tag{41.43}$$

between the two turning points where the energy line crosses the parabolic potential-energy curve. As you've learned, this classical description fails if m represents an atomic particle, such as an electron or an atom. In that case, we need to solve the Schrödinger equation to find the wave functions.

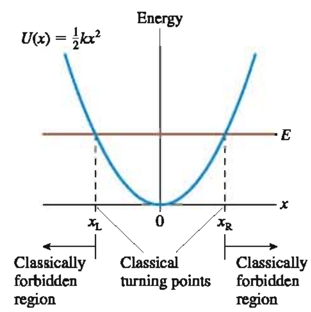


FIGURE 41.20 The potential energy of a harmonic oscillator.

The Schrödinger equation for a quantum harmonic oscillator is

$$\frac{d^2\psi}{dx^2} = -\frac{2m}{\hbar^2}\left(E - \frac{1}{2}kx^2\right)\psi(x) \tag{41.44}$$

where we used $U(x) = \frac{1}{2}kx^2$. We will assert, without deriving them, that the wave functions of the first three states are

$$\begin{aligned}\psi_1(x) &= A_1 e^{-x^2/2b^2}\\ \psi_2(x) &= A_2\frac{x}{b}e^{-x^2/2b^2}\\ \psi_3(x) &= A_3\left(1 - \frac{2x^2}{b^2}\right)e^{-x^2/2b^2}\end{aligned} \tag{41.45}$$

where

$$b = \sqrt{\frac{\hbar}{m\omega}} \tag{41.46}$$

The constant b has dimensions of length. We will leave it as a homework problem for you to show that b is the classical turning point of an oscillator in the $n = 1$ ground state. The constants A_1, A_2, and A_3 are normalization constants. For example, A_1 can be found by requiring

$$\int_{-\infty}^{\infty} |\psi_1(x)|^2 dx = A_1^2 \int_{-\infty}^{\infty} e^{-x^2/b^2} dx = 1 \qquad (41.47)$$

The completion of this calculation also will be left as a homework problem.

As expected, stationary states of a quantum harmonic oscillator exist only for certain discrete energy levels, the quantum states of the oscillator. The allowed energies are given by the simple equation

$$E_n = \left(n - \frac{1}{2}\right)\hbar\omega \qquad n = 1, 2, 3, \ldots \qquad (41.48)$$

where ω is the classical angular frequency, Equation 41.43, and n is the quantum number.

NOTE ▶ The ground-state energy of the quantum harmonic oscillator is $E_1 = \frac{1}{2}\hbar\omega$. An atomic mass on a spring can *not* be brought to rest. This is a consequence of the uncertainty principle. ◀

FIGURE 41.21 shows the first three energy levels and wave functions of a quantum harmonic oscillator. Notice that the energy levels are equally spaced by $\Delta E = \hbar\omega$. This result differs from the particle in a box, where the energy levels get increasingly farther apart. Also notice that the wave functions, like those of the finite potential well, extend beyond the turning points into the classically forbidden region.

FIGURE 41.21 The first three energy levels and wave functions of a quantum harmonic oscillator.

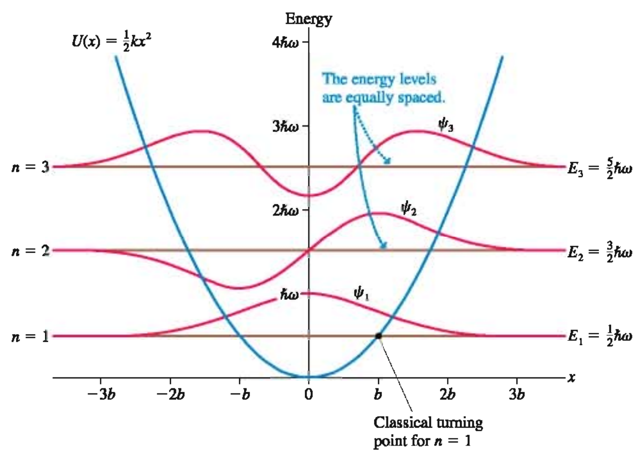

FIGURE 41.22 The quantum and classical probability densities for the $n = 11$ state of a quantum harmonic oscillator.

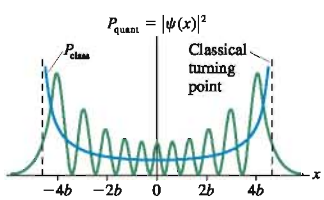

FIGURE 41.22 shows the probability density $|\psi(x)|^2$ for the $n = 11$ state of a quantum harmonic oscillator. Notice how the node spacing and the amplitude both increase as the particle moves away from the equilibrium position at $x = 0$. This is consistent with item 3 of Tactics Box 41.1. The particle slows down as it moves away from the origin, causing its de Broglie wavelength *and* the probability of finding it to increase.

Section 41.5 introduced the classical probability density $P_{class}(x)$ and noted that a classical particle is most likely to be found where it is moving the slowest. Figure 41.22

shows $P_{class}(x)$ for a classical particle with the same total energy as the $n = 11$ quantum state. You can see that *on average* the quantum probability density $|\psi(x)|^2$ mimics the classical probability density. This is just what the correspondence principle leads us to expect.

EXAMPLE 41.9 Light emission by an oscillating electron

An electron in a harmonic-oscillator potential well emits light of wavelength 600 nm as it jumps from one level to the next lowest level. What is the spring constant of the restoring force?

MODEL The electron is a quantum harmonic oscillator.

SOLVE A photon is emitted as the electron undergoes the quantum jump $n \rightarrow n - 1$. We can use Equation 41.48 for the energy levels to find that the electron loses energy

$$\Delta E = E_n - E_{n-1} = \left(n - \frac{1}{2}\right)\hbar\omega_e - \left(n - 1 - \frac{1}{2}\right)\hbar\omega_e = \hbar\omega_e$$

$\Delta E = \hbar\omega_e$ for *all* transitions, independent of n, because the energy levels of the quantum harmonic oscillator are equally spaced. We need to distinguish the harmonic oscillations of the electron from the oscillations of the light wave, hence the subscript e on ω_e.

The emitted photon has energy $E_{photon} = hf_{ph} = \Delta E$. Thus

$$\hbar\omega_e = \frac{h}{2\pi}\omega_e = hf_{ph} = \frac{hc}{\lambda}$$

The wavelength of the light is $\lambda = 600$ nm, so the classical angular frequency of the oscillating electron is

$$\omega_e = 2\pi\frac{c}{\lambda} = 3.14 \times 10^{15} \text{ rad/s}$$

The electron's angular frequency is related to the spring constant of the restoring force by

$$\omega_e = \sqrt{\frac{k}{m}}$$

Thus $k = m\omega_e^2 = 9.0$ N/m.

Molecular Vibrations

We've made many uses of the idea that atoms are held together by spring-like molecular bonds. We've always assumed that the bonds could be modeled as classical springs. The classical model is acceptable for some purposes, but it fails to explain some important features of molecular vibrations. Not surprisingly, the quantum harmonic oscillator is a better model of a molecular bond.

FIGURE 41.23 shows the potential energy of two atoms connected by a molecular bond. Nearby atoms attract each other through a polarization force, much as a charged rod picks up small pieces of paper. If the atoms get too close, a *repulsive* force between the negative electrons pushes them away. The equilibrium separation at which the attractive and repulsive forces are balanced is r_0, and two classical atoms would be at rest at this separation. But quantum particles, even in their lowest energy state, have $E > 0$. Consequently, the molecule *vibrates* as the two atoms oscillate back and forth along the bond.

U_{dissoc} is the energy at which the molecule will *dissociate* and the two atoms will fly apart. Dissociation can occur at very high temperatures or after the molecule has absorbed a high-energy (ultraviolet) photon, but under typical conditions a molecule has energy $E \ll U_{dissoc}$. In other words, the molecule is in an energy level near the bottom of the potential well.

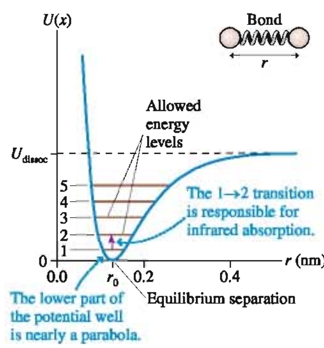
You can see that the lower portion of the potential well is very nearly a parabola. Consequently, we can model a molecular bond as a quantum harmonic oscillator. The energy associated with the molecular vibration is quantized and can have *only* the values

$$E_{vib} \approx \left(n - \frac{1}{2}\right)\hbar\omega \qquad n = 1, 2, 3, \ldots \tag{41.49}$$

where ω is the angular frequency with which the atoms would vibrate if the bond were a classical spring. The molecular potential-energy curve is not exactly that of a harmonic oscillator, hence the $\approx$ sign, but the model is very good for low values of the quantum number n. The energy levels calculated by Equation 41.49 are called the **vibrational energy levels** of the molecule. The first few vibrational energy levels are shown in Figure 41.23.

At room temperature, most molecules are in the $n = 1$ vibrational ground state. Their vibrational motion can be excited by absorbing photons of frequency $f = \Delta E/h$.

FIGURE 41.23 The potential energy of a molecular bond and a few of the allowed energies.



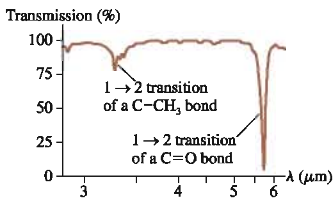


FIGURE 41.24 The absorption spectrum of acetone.

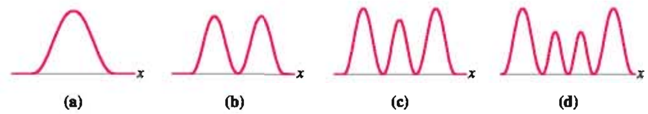
This frequency is usually in the infrared region of the spectrum, and these *vibrational transitions* give each molecule a unique and distinctive infrared absorption spectrum.

As an example, FIGURE 41.24 shows the infrared absorption spectrum of acetone. The vertical axis is the percentage of the light intensity passing all the way through the sample. The sample is essentially transparent at most wavelengths (transmission $\approx 100\%$), but there are two prominent absorption features. The transmission drops to $\approx 75\%$ at $\lambda = 3.3\ \mu m$ and to a mere 7% at $\lambda = 5.8\ \mu m$. The 3.3 μm absorption is due to the $n = 1$ to $n = 2$ transition in the vibration of a C–CH$_3$ carbon-methyl bond. The 5.8 μm absorption is the $1 \rightarrow 2$ transition of a vibrating C=O carbon-oxygen double bond.

Absorption spectra such as this are known for thousands of molecules, and chemists routinely use absorption spectroscopy to identify the chemicals in a sample. A specific bond has the same absorption wavelength regardless of the larger molecule in which it is embedded; thus the presence of that absorption wavelength is a "signature" that the bond is present within a molecule.

STOP TO THINK 41.5 Which probability density represents a quantum harmonic oscillator with $E = \frac{5}{2}\hbar\omega$?



41.9 More Quantum Models

In this section we'll look at two more examples of quantum-mechanical models.

A Particle in a Capacitor

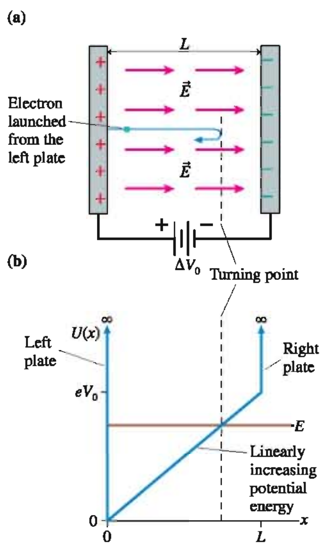


FIGURE 41.25 An electron in a capacitor.

Many semiconductor devices are designed to confine electrons within a layer only a few nanometers thick. If a potential difference is applied across the layer, the electrons act very much as if they are trapped within a microscopic capacitor.

FIGURE 41.25a shows two capacitor plates separated by distance L. The left plate is positive, so the electric field points to the right with strength $E = \Delta V_0/L$. Because of its negative charge, an electron launched from the left plate is slowed by a *retarding* force. The electron makes it across to the right plate if it starts with sufficient kinetic energy; otherwise, it reaches a turning point and then is pushed back toward the positive plate.

This classical analysis is a valid model of a macroscopic capacitor. But if L becomes sufficiently small, comparable to the de Broglie wavelength of an electron, then the wave-like properties of the electron cannot be ignored. We need a quantum-mechanical model.

Let's establish a coordinate system with $x = 0$ at the left plate and $x = L$ at the right plate. We define the electric potential to be zero at the positive plate. The potential *decreases* in the direction of the field, so the potential inside the capacitor (see Section 29.5) is

$$V(x) = -Ex = -\frac{\Delta V_0}{L}x$$

The electron, with charge $q = -e$, has potential energy

$$U(x) = qV(x) = +\frac{e\Delta V_0}{L}x \qquad 0 < x < L \tag{41.50}$$

This potential energy increases linearly for $0 < x < L$. If we assume that the capacitor plates act like the walls of a rigid box, then $U(x) \to \infty$ at $x = 0$ and $x = L$.

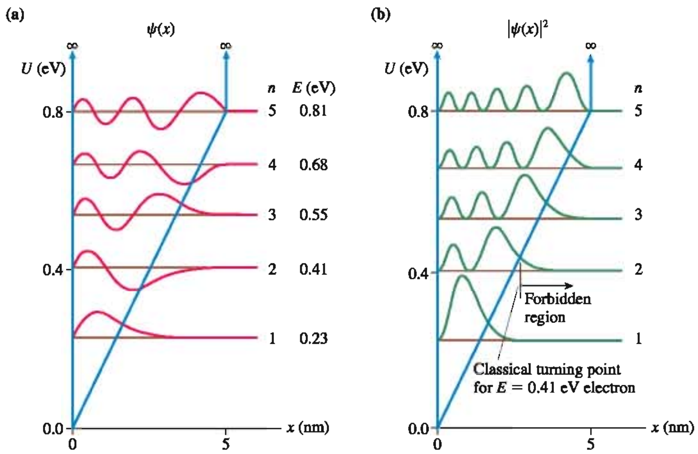
FIGURE 41.25b shows the electron's potential-energy function. It is the particle-in-a-rigid-box potential with a sloping "floor" due to the electric field. The figure also shows the total energy line E of an electron in the capacitor. The energy is purely kinetic at $x = 0$, where $K = E$, but it is converted to potential energy as the electron moves to the right. The right turning point occurs where the energy line E crosses the potential-energy curve $U(x)$. If the electron is a classical particle, it must reverse direction at this point.

NOTE ▶ This is also the shape of the potential energy for a microscopic bouncing ball that is trapped between a floor at $y = 0$ and a ceiling at $y = L$. ◀

It is physically impossible for an electron to be outside the capacitor, so the wave function must be zero for $x < 0$ and $x > L$. The continuity of ψ requires the same boundary conditions as for a particle in a rigid box: $\psi = 0$ at $x = 0$ and at $x = L$. The wave functions inside the capacitor are too complicated to find by guessing, so we have solved the Schrödinger equation numerically and will present the results graphically.

FIGURE 41.26 shows the wave functions and probability densities for the first five quantum states of an electron confined in a 5.0-nm-thick layer that has a 0.80 V potential difference across it. Each allowed energy is represented as a horizontal line, with the numerical values shown on the right. They range from $E_1 = 0.23$ eV up to $E_5 = 0.81$ eV. An electron *must* have one of the allowed energies shown in the figure. An electron cannot have $E = 0.30$ eV in this capacitor because no de Broglie wave with that energy can match the necessary boundary conditions.

FIGURE 41.26 Energy levels, wave functions, and probability densities for an electron in a 5.0-nm-wide capacitor with a 0.80 V potential difference.



NOTE ▶ Remember that each wave function and probability density is graphed as if its energy line is the zero of the y-axis. ◀

We can make some observations about the Schrödinger equation solutions:

1. The energies E_n become more closely spaced as n increases. This behavior is in contrast to the particle in a box, for which E_n became more widely spaced.
2. The spacing between the nodes of a wave function is not constant but increases toward the right. This is because an electron on the right side of the capacitor has less kinetic energy and thus a slower speed and a larger de Broglie wavelength.

3. The height of the probability density $|\psi|^2$ increases toward the right. That is, we are more likely to find the electron on the right side of the capacitor than on the left. But this also makes sense if, classically, the electron is moving more slowly when on the right side and thus spending more time there than on the left side.
4. The electron penetrates *beyond* the classical turning point into the classically forbidden region.

EXAMPLE 41.10 The emission spectrum of an electron in a capacitor

What are the wavelengths of photons emitted by electrons in the $n = 4$ state of Figure 41.26?

SOLVE Photon emission occurs as the electrons make $4 \rightarrow 3$, $4 \rightarrow 2$, and $4 \rightarrow 1$ quantum jumps. In each case, the photon frequency is $f = \Delta E/h$ and the wavelength is

$$\lambda = \frac{c}{f} = \frac{hc}{\Delta E}$$

The energies of the quantum jumps, which can be read from Figure 41.26a, are $\Delta E_{4\rightarrow 3} = 0.13$ eV, $\Delta E_{4\rightarrow 2} = 0.27$ eV, and $\Delta E_{4\rightarrow 1} = 0.45$ eV. Thus

$$\lambda_{4\rightarrow 3} = 9500 \text{ nm} = 9.5\ \mu\text{m}$$

$$\lambda_{4\rightarrow 2} = 4600 \text{ nm} = 4.6\ \mu\text{m}$$

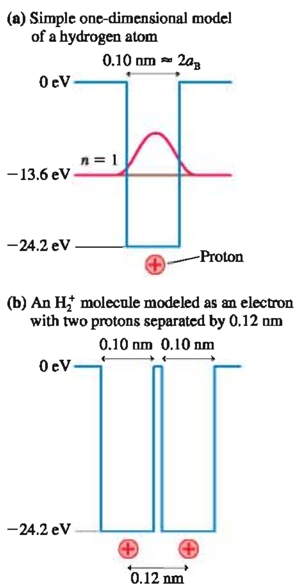
$$\lambda_{4\rightarrow 1} = 2800 \text{ nm} = 2.8\ \mu\text{m}$$

ASSESS The $n = 4$ electrons in this device emit three distinct infrared wavelengths.

The Covalent Bond

You probably recall from chemistry that a **covalent molecular bond,** such as the bond between the two atoms in molecules such as H_2 and O_2, is a bond in which the electrons are shared between the atoms. The basic idea of covalent bonding can be understood with a one-dimensional quantum-mechanical model.

FIGURE 41.27 A molecule can be modeled as two closely spaced potential wells, one representing each atom.



The simplest molecule, the hydrogen molecular ion H_2^+, consists of two protons and one electron. Although it seems surprising that such a system could be stable, the two protons form a molecular bond with one electron. This is the simplest covalent bond.

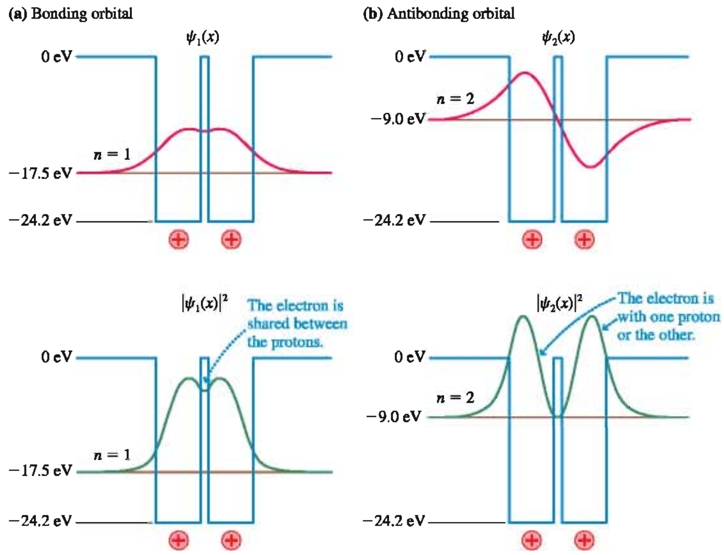
How can we model the H_2^+ ion? To begin, FIGURE 41.27a shows a one-dimensional model of a hydrogen *atom* in which the electron's Coulomb potential energy, with its $1/r$ dependence, has been approximated by a finite potential well of width 0.10 nm ($\approx 2a_B$) and depth 24.2 eV. You learned in Chapter 39 that an electron in the ground state of the Bohr hydrogen atom orbits the proton with radius $r_1 = a_B$ (the Bohr radius) and energy $E_1 = -13.6$ eV. A numerical solution of the Schrödinger equation finds that the ground-state energy of this finite potential well is $E_1 = -13.6$ eV. This model of a hydrogen atom is oversimplified, but it does have the correct size and ground-state energy.

We can model H_2^+ by bringing two of these potential wells close together. The molecular bond length of H_2^+ is known to be ≈ 0.12 nm, so FIGURE 41.27b shows potential wells with 0.12 nm between their centers. This is a model of H_2^+, not a complete H_2 molecule, because this is the potential energy of a single electron. (Modeling H_2 is more complex because we would need to consider the repulsion between the two electrons.)

FIGURE 41.28 shows the allowed energies, wave functions, and probability densities for an electron with this potential energy. The $n = 1$ wave function has a high probability of being found within the classically forbidden region *between* the two protons. In other words, an electron in this quantum state really is "shared" by the protons and spends most of its time between them.

In contrast, an electron in the $n = 2$ energy level has zero probability of being found between the two protons because the $n = 2$ wave function has a node at the center. The probability density shows that an $n = 2$ electron is "owned" by one proton or the other rather than being shared.

FIGURE 41.28 The wave functions and probability densities of the electron in H_2^+.



To learn the consequences of these wave functions we need to calculate the total energy of the molecule: $E_{\text{mol}} = E_{\text{p-p}} + E_{\text{elec}}$. The $n = 1$ and $n = 2$ energies shown in Figure 41.28 are the energies E_{elec} of the electron. At the same time, the protons repel each other and have electric potential energy $E_{\text{p-p}}$. It's not hard to calculate that $E_{\text{p-p}} = 12.0$ eV for two protons separated by 0.12 nm. Thus

$$E_{\text{mol}} = E_{\text{p-p}} + E_{\text{elec}} = \begin{cases} 12.0\text{ eV} - 17.5\text{ eV} = -5.5\text{ eV} & n = 1 \\ 12.0\text{ eV} - \ \ 9.0\text{ eV} = +3.0\text{ eV} & n = 2 \end{cases}$$

The $n = 1$ molecular energy is less than zero, showing that this is a *bound state*. The $n = 1$ wave function is called a **bonding molecular orbital.** Although the protons repel each other, the shared electron provides sufficient "glue" to hold the system together. The $n = 2$ molecular energy is positive, so this is *not* a bound state. The system would be more stable as a hydrogen atom and a distant proton. The $n = 2$ wave function is called an **antibonding molecular orbital.**

Both E_{elec} and $E_{\text{p-p}}$ depend on the separation between the protons, which we assumed to be 0.12 nm in this calculation. If we were to calculate and graph E_{mol} for many different values of the proton separation, the graph would look like the molecular-bond energy curve shown in Figure 41.23. In other words, a molecular bond has an equilibrium length where the bond energy is a minimum *because* of the interplay between $E_{\text{p-p}}$ and E_{elec}.

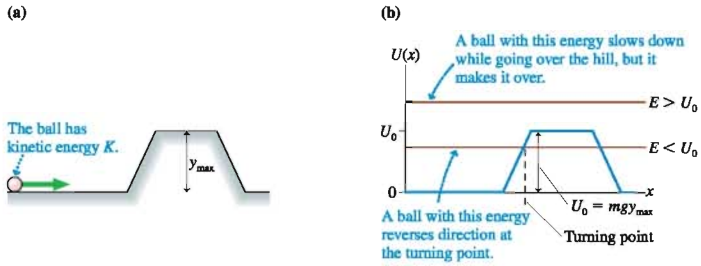
Although real molecular wave functions are more complex than this one-dimensional model, the $n = 1$ wave function captures the essential idea of a covalent bond. Notice that a "classical" molecule cannot have a covalent bond because the electron would not be able to exist in the classically forbidden region. Covalent bonds can be understood only within the context of quantum mechanics. In fact, the explanation of molecular bonds was one of the earliest successes of quantum mechanics.

41.10 Quantum-Mechanical Tunneling

20.4 Activ ONLINE Physics

FIGURE 41.29a shows a ball rolling toward a hill. A ball with sufficient kinetic energy can go over the top of the hill, slowing down as it ascends and speeding up as it rolls down the other side. A ball with insufficient energy rolls partway up the hill, then reverses direction and rolls back down.

FIGURE 41.29 A hill is an energy barrier to a rolling ball.



We can think of the hill as an "energy barrier" of height $U_0 = mgy_{max}$. As FIGURE 41.29b shows, a ball incident from the left with energy $E > U_0$ can go over the barrier (i.e., roll over the hill), but a ball with $E < U_0$ will reflect from the energy barrier at the turning point. According to the laws of classical physics, a ball that is incident on the energy barrier from the left with $E < U_0$ will never be found on the right side of the barrier.

NOTE ▶ Figure 41.29b is not a "picture" of the energy barrier. And when we say that a ball with energy $E > U_0$ can go "over" the barrier, we don't mean that the ball is thrown from a higher elevation in order to go over the top of the hill. The ball rolls *on the ground* the entire time, as Figure 41.29a shows, and Figure 41.29b describes the kinetic and potential energy of the ball as it rolls. A higher total energy line means a larger initial kinetic energy, not a higher elevation. ◀

FIGURE 41.30 A quantum particle can penetrate through the energy barrier.

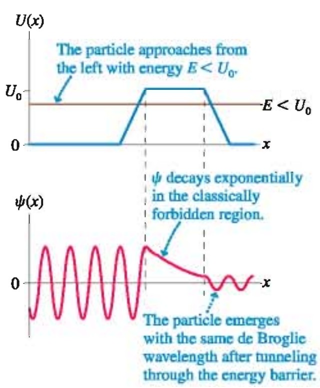


FIGURE 41.30 shows the situation from the perspective of quantum mechanics. As you've learned, quantum particles can penetrate with an exponentially decreasing wave function into the classically forbidden region of an energy barrier. Suppose that the barrier is very narrow. Although the wave function decreases within the barrier, starting at the classical turning point, it hasn't vanished when it reaches the other side. In other words, there is some probability that a quantum particle will pass *through* the barrier and emerge on the other side!

It is very much as if the ball of Figure 41.29a gets to the turning point and then, instead of reversing direction and rolling back down, tunnels its way *through* the hill and emerges on the other side. Although this feat is strictly forbidden in classical mechanics, it is apparently acceptable behavior for quantum particles. The process is called **quantum-mechanical tunneling.**

The process of tunneling through a potential-energy barrier is one of the strangest and most unexpected predictions of quantum mechanics. Yet it does happen, and you will see that it even has many practical applications.

NOTE ▶ The word "tunneling" is used as a metaphor. If a classical particle really did tunnel, it would expend energy doing so and emerge on the other side with less energy. Quantum-mechanical tunneling requires no expenditure of energy. The total energy line is at the same height on both sides of the barrier. A particle that tunnels through a barrier emerges with *no* loss of energy. That is why the de Broglie wavelength is the same on both sides of the potential barrier in Figure 41.30. ◀

To simplify our analysis of tunneling, FIGURE 41.31 shows an idealized energy barrier of height U_0 and width w. We've superimposed the wave function on top of the energy diagram so that you can see how it aligns with the potential energy. The wave function to the left of the barrier is a sinusoidal oscillation with amplitude A_L. The wave function *within* the barrier is the decaying exponential we found in Equation 41.40:

$$\psi_{in}(0 \le x \le w) = \psi_{edge} e^{-x/\eta} = A_L e^{-x/\eta} \tag{41.51}$$

where we've assumed $\psi_{edge} = A_L$. The penetration distance η was given in Equation 41.41 as

$$\eta = \frac{\hbar}{\sqrt{2m(U_0 - E)}}$$

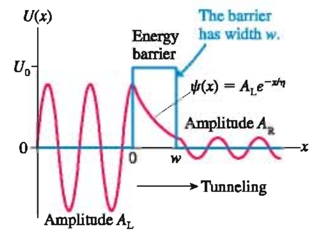

FIGURE 41.31 Tunneling through an idealized energy barrier.

NOTE ▶ You *must* use SI units when calculating values of η. Energies must be in J and $\hbar$ in J s. The penetration distance η has units of meters. ◀

The wave function decreases exponentially within the barrier, but before it can decay to zero, it emerges again on the right side ($x > w$) as an oscillation with amplitude

$$A_R = \psi_{in}(\text{at } x = w) = A_L e^{-w/\eta} \tag{41.52}$$

The probability that the particle is to the left of the barrier is proportional to $|A_L|^2$, and the probability of finding it to the right of the barrier is proportional to $|A_R|^2$. Thus the probability that a particle striking the barrier from the left will emerge on the right is

$$P_{tunnel} = \frac{|A_R|^2}{|A_L|^2} = (e^{-w/\eta})^2 = e^{-2w/\eta} \tag{41.53}$$

This is the probability that a particle will tunnel through the energy barrier.

Now, our analysis, we have to say, has not been terribly rigorous. For example, we assumed that the oscillatory wave functions on the left and the right were exactly at a maximum where they reached the barrier at $x = 0$ and $x = w$. There is no reason this has to be the case. We have taken other liberties, which experts will spot, but—fortunately—it really makes no difference. Our result, Equation 41.53, turns out to be perfectly adequate for most applications of tunneling.

Because the tunneling probability is an exponential function, it is *very* sensitive to the values of w and η. The tunneling probability can be substantially reduced by even a small increase in the thickness of the barrier. The parameter η, which measures how far the particle can penetrate into the barrier, depends both on the particle's mass and on $U_0 - E$. A particle with E only slightly less than U_0 will have a larger value of η and thus a larger tunneling probability than will an identical particle with less energy.

EXAMPLE 41.11 Electron tunneling

a. Find the probability that an electron will tunnel through a 1.0-nm-wide energy barrier if the electron's energy is 0.10 eV less than the height of the barrier.
b. Find the tunneling probability if the barrier in part a is widened to 3.0 nm.
c. Find the tunneling probability if the electron in part a is replaced by a proton with the same energy.

SOLVE a. An electron with energy 0.10 eV less than the height of the barrier has $U_0 - E = 0.10\text{ eV} = 1.60 \times 10^{-20}\text{ J}$. Thus its penetration distance is

$$\eta = \frac{\hbar}{\sqrt{2m(U_0 - E)}} = \frac{1.05 \times 10^{-34}\text{ Js}}{\sqrt{2(9.11 \times 10^{-31}\text{ kg})(1.60 \times 10^{-20}\text{ J})}} = 6.18 \times 10^{-10}\text{ m} = 0.618\text{ nm}$$

Continued

The probability that this electron will tunnel through a barrier of width $w = 1.0$ nm is

$$P_{\text{tunnel}} = e^{-2w/\eta} = e^{-2(1.0\text{ nm})/(0.618\text{ nm})} = 0.039 = 3.9\%$$

b. Changing the width to $w = 3.0$ nm has no effect on η. The new tunneling probability is

$$P_{\text{tunnel}} = e^{-2w/\eta} = e^{-2(3.0\text{ nm})/(0.618\text{ nm})} = 6.0 \times 10^{-5}$$
$$= 0.006\%$$

Increasing the width by a factor of 3 decreases the tunneling probability by a factor of 660!

c. A proton is more massive than an electron. Thus a proton with $U_0 - E = 0.10$ eV has $\eta = 0.014$ nm. Its probability of tunneling through a 1.0-nm-wide barrier is

$$P_{\text{tunnel}} = e^{-2w/\eta} = e^{-2(1.0\text{ nm})/(0.014\text{ nm})} \approx 1 \times 10^{-64}$$

For practical purposes, the probability that a proton will tunnel through this barrier is zero.

ASSESS If the probability of a proton tunneling through a mere 1 nm is only 10^{-64}, you can see that a macroscopic object will "never" tunnel through a macroscopic distance!

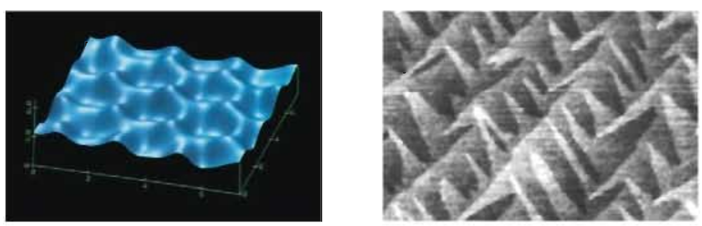
Quantum-mechanical tunneling seems so obscure that it is hard to imagine practical applications. Surprisingly, there are many. We will look at two: the scanning tunneling microscope and the resonant tunneling diode.

The Scanning Tunneling Microscope

Diffraction limits the resolution of an optical microscope to objects no smaller than about a wavelength of light—roughly 500 nm. This is more than 1000 times the size of an atom, so there is no hope of resolving atoms or molecules via optical microscopy. Electron microscopes are similarly limited by the de Broglie wavelength of the electrons. Their resolution is much better than an optical microscope, but still not quite at the level of resolving individual atoms.

This situation changed dramatically in 1981 with the invention of the **scanning tunneling microscope,** or STM as it is usually called. The STM allowed scientists, for the first time, to "see" surfaces literally atom by atom. FIGURE 41.32 shows two pictures taken with a STM. In one you can see individual atoms of carbon on the surface of graphite. The other shows a somewhat less magnified surface of silicon. These pictures and many others you have likely seen (but may not have known where they came from) are stupendous, but how are they made?

FIGURE 41.32 Two pictures made with a scanning tunneling microscope.



Individual atoms of carbon on the surface of graphite

The surface of silicon

FIGURE 41.33a on the next page shows how the scanning tunneling microscope works. A conducting probe with a *very* sharp tip, just a few atoms wide, is brought to within a few tenths of a nanometer of a surface. Preparing the tips and controlling the spacing are both difficult technical challenges, but scientists have learned how to do both. Once positioned, the probe can mechanically scan back and forth across the surface.

When we analyzed the photoelectric effect, you learned that electrons are bound inside metals by an amount of energy called the *work function* E_0. A typical work function is 4 or 5 eV. This is the energy that must be supplied—by a photon or

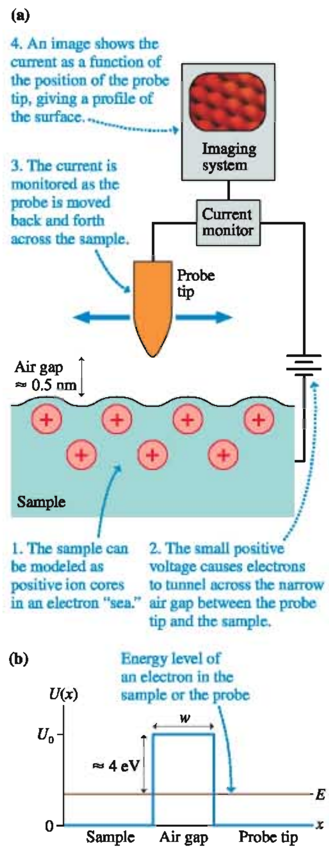
otherwise—to remove an electron from the metal. In other words, the electron's energy in the metal is E_0 less than its energy outside the metal.

This fact is the basis for the potential-energy diagram of FIGURE 41.33b. The small air gap between the sample and the probe tip is a potential-energy barrier. The energy of an electron in the metal of the sample or the probe tip is lower than the energy of an electron in the air by ≈ 4 eV, the work function. The absorption of a photon with $E_{photon} > 4$ eV would lift the electron *over* the barrier, from the sample to the probe. This is just the photoelectric effect. Alternatively, electrons can tunnel *through* the barrier if it is sufficiently narrow. This creates a ***tunneling current*** from the sample into the probe.

In operation, the tunneling current is recorded as the probe tip scans across the surface. You saw above that the tunneling current is extremely sensitive to the barrier thickness. As the tip scans over the position of an atom, the gap decreases by ≈ 0.1 nm and the current increases. The gap is larger when the tip is between atoms, so the current drops. Today's STMs can sense changes in the gap of as little as 0.001 nm, or about 1% of an atomic diameter! The images you see, such as those in Figure 41.32, are computer-generated from the current measurements at each position.

The STM has revolutionized the science and engineering of microscopic objects. STMs are now used to study everything from how surfaces corrode and oxidize, a topic of great practical importance in engineering, to how biological molecules are structured. Another example of quantum mechanics working for you!

FIGURE 41.33 A scanning tunneling microscope.



The Resonant Tunneling Diode

The semiconductor diode laser that we examined in Section 41.6 had a narrow GaAs layer surrounded by wide layers of GaAlAs. Because an electron's potential energy is ≈ 0.3 eV less in GaAs than in GaAlAs, this structure provides a quantum well in which electrons are confined in a single energy level.

Suppose we manufacture a device in which a thin layer of GaAs is surrounded by still thinner layers of GaAlAs, only a few nanometers thick. FIGURE 41.34a is the potential-energy diagram of an electron in such a device. Because the GaAlAs layers are very thin, an electron inside the quantum well can tunnel through to the outside.

Conversely, an electron coming from the outside and impinging on the GaAlAs barrier might tunnel *into* the quantum well. However, tunneling into the well from the outside is hindered by a serious energy mismatch. An electron inside the quantum well *must* have one of the allowed energies. Typically there is a single allowed quantum state with $E_1 \approx 0.15$ eV. Electrons on the outside have thermal energy

$$E_{th} \approx \frac{3}{2}k_BT = 6.0 \times 10^{-21}\ \text{J} = 0.040\ \text{eV}$$

at room temperature. Tunneling may be a strange phenomenon, but energy does still have to be conserved. An electron approaching the barrier with $E \approx 0.04$ eV cannot tunnel inside unless there is a quantum state with this allowed energy.

FIGURE 41.34 Electron potential energy in a resonant tunneling diode.

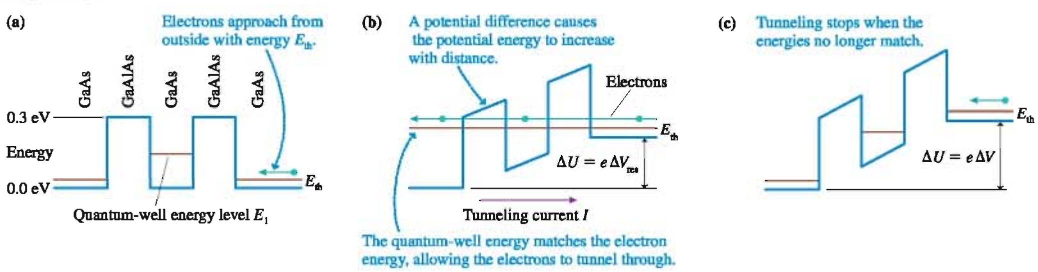


FIGURE 41.34b shows the effect of placing a potential difference ΔV across the three layers of the device. As the potential difference is increased, it will reach a value ΔV_{res} at which the energy level inside the quantum well matches the energy of an electron approaching from the right. We then have a *resonance*, much as when an external driving frequency matches the natural frequency of an oscillator.

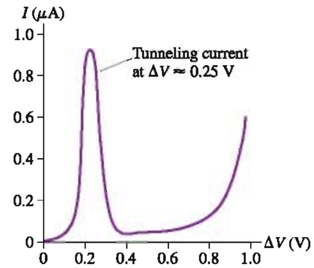
Once the energies match, electrons approaching from the right can easily tunnel into the quantum well. They then tunnel through the opposite barrier and emerge on the left with kinetic energy $K \approx e\Delta V$. In other words, there is a current through the device when the potential difference is ΔV_{res}. This device is called a **resonant tunneling diode.**

FIGURE 41.35 Experimental measurement of the current-voltage characteristics of a resonant tunneling diode.



Too high a voltage destroys the resonance. As FIGURE 41.34c shows, a large ΔV drops the energy level in the quantum well too low, so again electrons from the right side have no matching energy level into which they can tunnel. Charge flows through a resonant tunneling diode for only a small range of voltages near ΔV_{res}.

FIGURE 41.35 is an experimental current-voltage graph for a device having a 4 nm GaAs quantum well surrounded by 10-nm-wide GaAlAs barriers. There is a small range of voltages around 0.25 volts for which the current shoots up by a factor of 10. This is ΔV_{res}, and the current is due to electrons tunneling through the diode. The current then drops back to near zero by the time $\Delta V = 0.40$ V. (The current increase for $\Delta V > 0.7$ V is "normal" diode behavior. A resonant tunneling diode would not be operated with voltages that large.)

The ability to drastically change current with just a small change in voltage makes tunneling diodes very useful in the digital circuits of high-speed computers. These diodes can also be used as very-high-speed oscillators, creating oscillating voltages with frequencies as high as 500 GHz.

STOP TO THINK 41.6 A particle with energy E approaches an energy barrier with height $U_0 > E$. If U_0 is slowly decreased, the probability that the particle reflects from the barrier

a. Increases.
b. Decreases.
c. Does not change.

SUMMARY

The goal of Chapter 41 has been to understand and apply the essential ideas of quantum mechanics.

General Principles

The Schrödinger Equation (the "law of psi")

$$\frac{d^2\psi}{dx^2} = -\frac{2m}{\hbar^2}[E - U(x)]\psi(x)$$

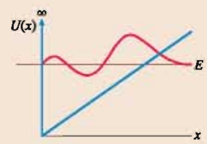
This equation determines the wave function $\psi(x)$ and, through $\psi(x)$, the probabilities of finding a particle of mass m with potential energy $U(x)$.

Boundary conditions

- $\psi(x)$ is a continuous function.
- $\psi(x) \rightarrow 0$ as $x \rightarrow \pm\infty$.
- $\psi(x) = 0$ in a region where it is physically impossible for the particle to be.
- $\psi(x)$ is normalized.

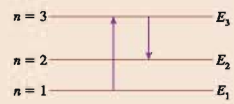
Shapes of wave functions

- The wave function oscillates in the region between the classical turning points.
- State n has n antinodes.
- Node spacing and amplitude increase as kinetic energy K decreases.
- $\psi(x)$ decays exponentially in a classically forbidden region.



Quantum-mechanical models are characterized by the particle's potential-energy function $U(x)$.

- Wave-function solutions exist for only certain values of E. Thus energy is quantized.
- Photons are emitted or absorbed in quantum jumps.



Important Concepts

Quantum-mechanical tunneling

A wave function can penetrate into a classically forbidden region with

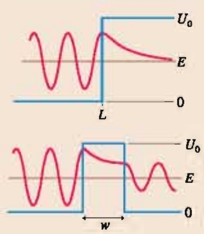
$$\psi(x) = \psi_{edge}e^{-(x-L)/\eta}$$

where the **penetration distance** is

$$\eta = \frac{\hbar}{\sqrt{2m(U_0 - E)}}$$

The probability of tunneling through a barrier of width w is

$$P_{tunnel} = e^{-2w/\eta}$$



The **correspondence principle** says that the quantum world blends smoothly into the classical world for high quantum numbers. This is seen by comparing $|\psi(x)|^2$ to the classical probability density

$$P_{class} = \frac{2}{Tv(x)}$$

P_{class} expresses the idea that a classical particle is more likely to be found where it is moving slowly.

Applications

Particle in a rigid box: $E_n = n^2\dfrac{h^2}{8mL^2}$ $\quad n = 1, 2, 3, \ldots$

Quantum harmonic oscillator: $E_n = (n - \frac{1}{2})\hbar\omega$ $\quad n = 1, 2, 3, \ldots$

Other applications were studied through numerical solution of the Schrödinger equation.

Terms and Notation

Schrödinger equation	bound state	bonding molecular orbital
quantum-mechanical model	penetration distance, η	antibonding molecular orbital
boundary conditions	quantum-well laser	quantum-mechanical tunneling
zero-point motion	gamma rays	scanning tunneling microscope (STM)
correspondence principle	quantum harmonic oscillator	resonant tunneling diode
potential well	vibrational energy levels	
classically forbidden regions	covalent molecular bond

Problem difficulty is labeled as | (straightforward) to ||| (challenging).

Problems labeled integrate significant material from earlier chapters.

CONCEPTUAL QUESTIONS

1. The correspondence principle says that the *average* behavior of a quantum system should begin to look like the Newtonian solution in the limit that the quantum number becomes very large. What is meant by "the *average* behavior" of a quantum system?
2. A particle in a potential well is in the $n = 5$ quantum state. How many peaks are in the probability density $P(x) = |\psi(x)|^2$?
3. What is the quantum number of the particle in FIGURE Q41.3? How can you tell?

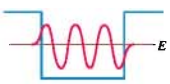

FIGURE Q41.3

4. Rank in order, from largest to smallest, the penetration distances η_a to η_c of the wave functions corresponding to the three energy levels in FIGURE Q41.4.

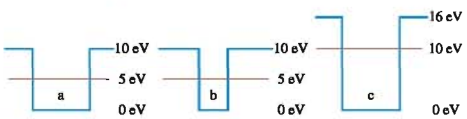

FIGURE Q41.4

5. Consider a quantum harmonic oscillator.
   a. What happens to the spacing between the nodes of the wave function as $|x|$ increases? Why?
   b. What happens to the heights of the antinodes of the wave function as $|x|$ increases? Why?
   c. Sketch a reasonably accurate graph of the $n = 8$ wave function of a quantum harmonic oscillator.
6. FIGURE Q41.6 shows two possible wave functions for an electron in a linear triatomic molecule. Which of these is a bonding orbital and which is an antibonding orbital? Explain how you can distinguish them.

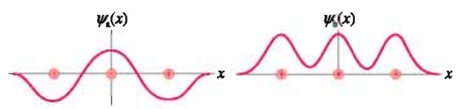

FIGURE Q41.6

7. Four quantum particles, each with energy E, approach the potential-energy barriers seen in FIGURE Q41.7 from the left. Rank in order, from largest to smallest, the tunneling probabilities $(P_{tunnel})_a$ to $(P_{tunnel})_d$.

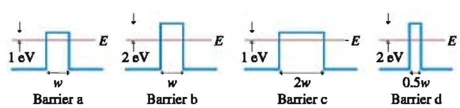

FIGURE Q41.7

EXERCISES AND PROBLEMS

Exercises

Sections 41.3–4 A Particle in a Rigid Box

1. || An electron in a rigid box absorbs light. The longest wavelength in the absorption spectrum is 600 nm. How long is the box?
2. | The electrons in a rigid box emit photons of wavelength 1484 nm during the $3 \rightarrow 2$ transition.
   a. What kind of photons are they—infrared, visible, or ultraviolet?
   b. How long is the box in which the electrons are confined?

3. | FIGURE EX41.3 shows the wave function of an electron in a rigid box. The electron energy is 6.0 eV. How long is the box?

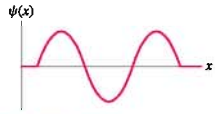

FIGURE EX41.3

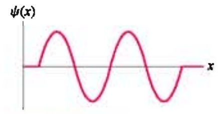

FIGURE EX41.4

4. | FIGURE EX41.4 shows the wave function of an electron in a rigid box. The electron energy is 12.0 eV. What is the energy of the electron's ground state?

Section 41.6 Finite Potential Wells

5. | Show that the penetration distance η has units of m.
6. | a. Sketch graphs of the probability density $|\psi(x)|^2$ for the four states in the finite potential well of Figure 41.14a. Stack them vertically, similar to the Figure 41.14a graphs of $\psi(x)$.
   b. What is the probability that a particle in the $n = 2$ state of the finite potential well will be found at the center of the well? Explain.
   c. Is your answer to part b consistent with what you know about waves? Explain.
7. | For a particle in a finite potential well of width L and depth U_0, what is the ratio of the probability Prob(in δx at $x = L + \eta$) to the probability Prob(in δx at $x = L$)?
8. | A finite potential well has depth $U_0 = 2.00$ eV. What is the penetration distance for an electron with energy (a) 0.50 eV, (b) 1.00 eV, and (c) 1.50 eV?
9. || An electron in a finite potential well has a 1.0 nm penetration distance into the classically forbidden region. How far below U_0 is the electron's energy?
10. | A helium atom is in a finite potential well. The atom's energy is 1.0 eV below U_0. What is the atom's penetration distance into the classically forbidden region?

Section 41.7 Wave-Function Shapes

11. | Sketch the $n = 6$ wave function for the potential energy shown in FIGURE EX41.11.

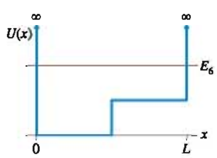

FIGURE EX41.11

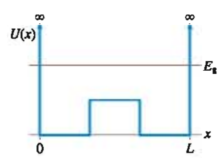

FIGURE EX41.12

12. | Sketch the $n = 8$ wave function for the potential energy shown in FIGURE EX41.12.
13. | The graph in FIGURE EX41.13 shows the potential-energy function $U(x)$ of a particle. Solution of the Schrödinger equation finds that the $n = 3$ level has $E_3 = 0.5$ eV and that the $n = 6$ level has $E_6 = 2.0$ eV.
    a. Redraw this figure and add to it the energy lines for the $n = 3$ and $n = 6$ states.
    b. Sketch the $n = 3$ and $n = 6$ wave functions. Show them as oscillating about the appropriate energy line.

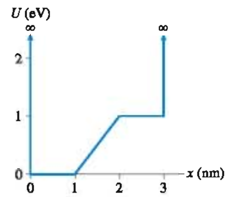

FIGURE EX41.13

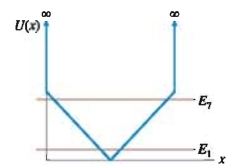

FIGURE EX41.14

14. | Sketch the $n = 1$ and $n = 7$ wave functions for the potential energy shown in FIGURE EX41.14.

Section 41.8 The Quantum Harmonic Oscillator

15. | An electron in a harmonic potential well emits a photon with a wavelength of 300 nm as it undergoes a $3 \rightarrow 2$ quantum jump. What wavelength photon is emitted in a $3 \rightarrow 1$ quantum jump?
16. || An electron is confined in a harmonic potential well that has a spring constant of 2.0 N/m.
    a. What are the first three energy levels of the electron?
    b. What wavelength photon is emitted if the electron undergoes a $3 \rightarrow 1$ quantum jump?
17. | An electron confined in a harmonic potential well emits a 1200 nm photon as it undergoes a $3 \rightarrow 2$ quantum jump. What is the spring constant of the potential well?
18. | An electron is confined in a harmonic potential well that has a spring constant of 12.0 N/m. What is the longest wavelength of light that the electron can absorb?
19. | Two adjacent energy levels of an electron in a harmonic potential well are known to be 2.0 eV and 2.8 eV. What is the spring constant of the potential well?

Section 41.10 Quantum-Mechanical Tunneling

20. || What is the probability that an electron will tunnel through a 0.45 nm gap from a metal to a STM probe if the work function is 4.0 eV?
21. || An electron approaches a 1.0-nm-wide potential-energy barrier of height 5.0 eV. What energy electron has a tunneling probability of (a) 10%, (b) 1.0%, and (c) 0.10%?

Problems

22. || A 2.0-μm-diameter water droplet is moving with a speed of 1.0 μm/s in a 20-μm-long box.
    a. Estimate the particle's quantum number.
    b. Use the correspondence principle to determine whether quantum mechanics is needed to understand the particle's motion or if it is "safe" to use classical physics.
23. || Suppose that $\psi_1(x)$ and $\psi_2(x)$ are both solutions to the Schrödinger equation for the same potential energy $U(x)$. Prove that the superposition $\psi(x) = A\psi_1(x) + B\psi_2(x)$ is also a solution to the Schrödinger equation.

24. ‖ Figure 41.26a modeled a hydrogen atom as a finite potential well with rectangular edges. A more realistic model of a hydrogen atom, although still a one-dimensional model, would be the electron + proton electrostatic potential energy in one dimension:

$$U(x) = -\frac{e^2}{4\pi\epsilon_0|x|}$$

a. Draw a graph of $U(x)$ versus x. Center your graph at $x = 0$.
b. Despite the divergence at $x = 0$, the Schrödinger equation can be solved to find energy levels and wave functions for the electron in this potential. Draw a horizontal line across your graph of part a about one-third of the way from the bottom to the top. Label this line E_2, then, on this line, sketch a plausible graph of the $n = 2$ wave function.
c. Redraw your graph of part a and add a horizontal line about two-thirds of the way from the bottom to the top. Label this line E_3, then, on this line, sketch a plausible graph of the $n = 3$ wave function.

25. ‖ a. Derive an expression for $\lambda_{2\to1}$, the wavelength of light emitted by a particle in a rigid box during a quantum jump from $n = 2$ to $n = 1$.
b. In what length rigid box will an electron undergoing a $2 \to 1$ transition emit light with a wavelength of 694 nm? This is the wavelength of a ruby laser.

26. ‖ Model an atom as an electron in a rigid box of length 0.100 nm, roughly twice the Bohr radius.
a. What are the four lowest energy levels of the electron?
b. Calculate all the wavelengths that would be seen in the emission spectrum of this atom due to quantum jumps between these four energy levels. Give each wavelength a label $\lambda_{n\to m}$ to indicate the transition.
c. Are these wavelengths in the infrared, visible, or ultraviolet portion of the spectrum?
d. The stationary states of the Bohr hydrogen atom have negative energies. The stationary states of this model of the atom have positive energies. Is this a physically significant difference? Explain.
e. Compare this model of an atom to the Bohr hydrogen atom. In what ways are the two models similar? Other than the signs of the energy levels, in what ways are they different?

27. ‖ Show that the normalization constant A_n for the wave functions of a particle in a rigid box has the value given in Equation 41.26.

28. ‖ A particle confined in a rigid one-dimensional box of length 10 fm has an energy level $E_n = 32.9$ MeV and an adjacent energy level $E_{n+1} = 51.4$ MeV.
a. Determine the values of n and $n + 1$.
b. Draw an energy-level diagram showing all energy levels from 1 through $n + 1$. Label each level and write the energy beside it.
c. Sketch the $n + 1$ wave function on the $n + 1$ energy level.
d. What is the wavelength of a photon emitted in the $n + 1 \to n$ transition? Compare this to a typical visible-light wavelength.
e. What is the mass of the particle? Can you identify it?

29. ‖ Consider a particle in a rigid box of length L. For each of the states $n = 1$, $n = 2$, and $n = 3$:
a. Sketch graphs of $|\psi(x)|^2$. Label the points $x = 0$ and $x = L$.
b. Where, in terms of L, are the positions at which the particle is *most* likely to be found?
c. Where, in terms of L, are the positions at which the particle is *least* likely to be found?
d. Determine, by examining your $|\psi(x)|^2$ graphs, if the probability of finding the particle in the left one-third of the box is less than, equal to, or greater than $\frac{1}{3}$. Explain your reasoning.
e. *Calculate* the probability that the particle will be found in the left one-third of the box.

30. ‖ For the quantum-well laser of Figure 41.16, *estimate* the probability that an electron will be found within one of the GaAlAs layers rather than in the GaAs layer. Explain your reasoning.

31. ‖ In a nuclear physics experiment, a proton is fired toward a $Z = 13$ nucleus with the diameter and neutron energy levels shown in Figure 41.17. The nucleus, which was initially in its ground state, subsequently emits a gamma ray with wavelength 1.73×10^{-4} nm. What was the *minimum* initial speed of the proton?
Hint: Don't neglect the proton-nucleus collision.

32. | Use the data from Figure 41.23 to calculate the first three vibrational energy levels of a C=O carbon-oxygen double bond.

33. | Verify that the $n = 1$ wave function $\psi_1(x)$ of the quantum harmonic oscillator really is a solution of the Schrödinger equation. That is, show that the right and left sides of the Schrödinger equation are equal if you use the $\psi_1(x)$ wave function.

34. | Show that the constant b used in the quantum-harmonic-oscillator wave functions (a) has units of length and (b) is the classical turning point of an oscillator in the $n = 1$ ground state.

35. ‖ a. Determine the normalization constant A_1 for the $n = 1$ ground-state wave function of the quantum harmonic oscillator. Your answer will be in terms of b.
b. Write an expression for the probability that a quantum harmonic oscillator in its $n = 1$ ground state will be found in the classically forbidden region.
c. (Optional) Use a numerical integration program to evaluate your probability expression of part b.
Hint: It helps to simplify the integral by making a change of variables to $u = x/b$.

36. ‖ a. Derive an expression for the classical probability density $P_{class}(x)$ for a simple harmonic oscillator with amplitude A.
b. Graph your expression between $x = -A$ and $x = +A$.
c. Interpret your graph. Why is it shaped as it is?

37. ‖ a. Derive an expression for the classical probability density $P_{class}(y)$ for a ball that bounces between the ground and height h. The collisions with the ground are perfectly elastic.
b. Graph your expression between $y = 0$ and $y = h$.
c. Interpret your graph. Why is it shaped as it is?

38. ‖ Figure 41.17 showed that a typical nuclear radius is 4.0 nm. As you'll learn in Chapter 43, a typical energy of a neutron bound inside the nuclear potential well is $E_n = -20$ MeV. To find out how "fuzzy" the edge of the nucleus is, what is the neutron's penetration distance into the classically forbidden region as a fraction of the nuclear radius?

39. ‖ Even the smoothest mirror finishes are "rough" when viewed at a scale of 100 nm. When two very smooth metals are placed in contact with each other, the actual distance between the surfaces varies from 0 nm at a few points of real contact to ≈100 nm. The average distance between the surfaces is ≈50 nm. The work function of aluminum is 4.3 eV. What is the probability that an electron will tunnel between two pieces of aluminum that are 50 nm apart? Give your answer as a power of 10.

40. ||| A proton's energy is 1.0 MeV below the top of 10-fm-wide energy barrier. What is the probability that the proton will tunnel through the barrier?

Challenge Problems

41. Consider a particle in a rigid box of length L with walls at $x = -L/2$ and $x = +L/2$.
    a. What is the wave function $\psi(x)$ for $x < -L/2$ and $x > L/2$? Explain.
    b. Write the Schrödinger equation in the region $-L/2 \leq x \leq L/2$ for a particle with energy E.
    c. Write down a general solution to the Schrödinger equation that is valid in the region $-L/2 \leq x \leq L/2$.
    d. What are the boundary conditions this wave function must satisfy?
    e. Apply the boundary conditions to determine the allowed energy levels. Note that there are two different ways to satisfy the boundary conditions, each giving a different set of wave functions and energy levels.
    f. Compare your results to the rigid box that was analyzed in this chapter. In what ways are the results the same and in what ways are they different? Are any differences physically meaningful?
42. A typical electron in a piece of metallic sodium has energy $-E_0$ compared to a free electron, where E_0 is the 2.7 eV work function of sodium.
    a. At what distance *beyond* the surface of the metal is the electron's probability density 10% of its value *at* the surface?
    b. How does this distance compare to the size of an atom?
43. A particle of mass m has the wave function $\psi(x) = Ax\exp(-x^2/a^2)$ when it is in an allowed energy level with $E = 0$.
    a. Draw a graph of $\psi(x)$ versus x.
    b. At what value or values of x is the particle most likely to be found?
    c. Find and graph the potential-energy function $U(x)$.
44. In most metals, the atomic ions form a regular arrangement called a *crystal lattice*. The conduction electrons in the sea of electrons move through this lattice. FIGURE CP41.44 is a one-dimensional model of a crystal lattice. The ions have mass m, charge e, and an equilibrium separation b.
    a. Suppose the middle charge is displaced a very small distance ($x \ll b$) from its equilibrium position while the outer charges remain fixed. Show that the net electric force on the middle charge is given approximately by

$$F = -\frac{e^2}{b^3 \pi \epsilon_0} x$$

    In other words, the charge experiences a linear restoring force.
    b. Suppose this crystal consists of aluminum ions with an equilibrium spacing of 0.30 nm. What are the energies of the four lowest vibrational states of these ions?
    c. What wavelength photons are emitted during quantum jumps between *adjacent* energy levels? Is this wavelength in the infrared, visible, or ultraviolet portion of the spectrum?

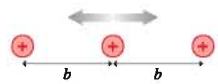

FIGURE CP41.44

45. a. What is the probability that an electron will tunnel through a 0.50 nm air gap from a metal to a STM probe if the work function is 4.0 eV?
    b. The probe passes over an atom that is 0.050 nm "tall." By what factor does the tunneling current increase?
    c. If a 10% current change is reliably detectable, what is the smallest height change the STM can detect?
46. Tennis balls traveling faster than 100 mph routinely bounce off tennis rackets. At some sufficiently high speed, however, the ball will break through the strings and keep going. The racket is a potential-energy barrier whose height is the energy of the slowest string-breaking ball. Suppose that a 100 g tennis ball traveling at 200 mph is just sufficient to break the 2.0-mm-thick strings. Estimate the probability that a 120 mph ball will tunnel through the racket without breaking the strings. Give your answer as a power of 10 rather than a power of e.

STOP TO THINK ANSWSERS

Stop to Think 41.1: $v_a = v_b > v_c$. The de Broglie wavelength is $\lambda = h/mv$, so slower particles have longer wavelengths. The wave amplitude is not relevant.

Stop to Think 41.2: c. The $n = 2$ state has a node in the middle of the box. The antinodes are centered in the left and right halves of the box.

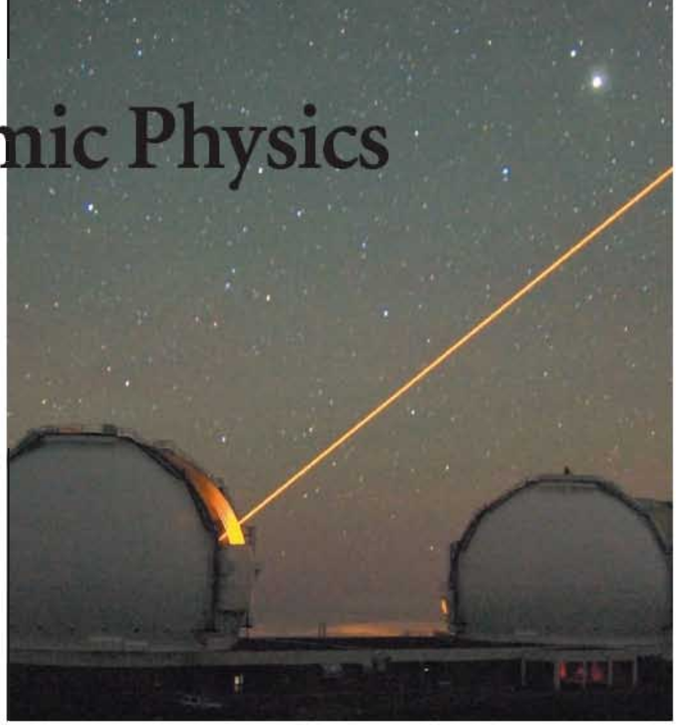
Stop to Think 41.3: $n = 4$. There are four antinodes and three nodes (excluding the ends).

Stop to Think 41.4: d. The wave function reaches zero abruptly on the right, indicating an infinitely high potential-energy wall. The exponential decay on the left shows that the left wall of the potential energy is *not* infinitely high. The node spacing and the amplitude increase steadily in going from right to left, indicating a *steadily* decreasing kinetic energy and thus a steadily increasing potential energy.

Stop to Think 41.5: c. $E = (n - \frac{1}{2})\hbar\omega$, so $\frac{5}{2}\hbar\omega$ is the energy of the $n = 3$ state. An $n = 3$ state has 3 antinodes.

Stop to Think 41.6: b. The probability of tunneling through the barrier increases as the difference between E and U_0 decreases. If the tunneling probability increases, the reflection probability must decrease.

42 Atomic Physics



Lasers are one of the most important applications of the quantum-mechanical properties of atoms and light.

▶ Looking Ahead
The goal of Chapter 42 is to understand the structure and properties of atoms. In this chapter you will learn to:

- Use a quantum-mechanical model of the hydrogen atom.
- Understand the idea of electron spin.
- Apply Schrödinger's quantum theory to multielectron atoms.
- Interpret atomic spectra.
- Understand how lasers work.

◀ Looking Back
The material in this chapter depends on an understanding of the Bohr model of atomic quantization and one-dimensional quantum mechanics. Please review:

- Sections 39.5 and 39.7 Bohr's model of quantization and the hydrogen atom.
- Sections 40.3 and 40.4 Interpreting and using wave functions.
- Sections 41.1 and 41.2 The basic ideas of quantum mechanics.

The problem of discovering the structure of atoms is one that we have continued to revisit. The first model of an atom we looked at, Rutherford's solar-system model, was purely classical. This model incorporated Rutherford's discovery of a very small nucleus, but otherwise it had almost no agreement with the experimental evidence about atoms. It could not explain their discrete spectra, nor could it explain why atoms are stable!

The Bohr model of the hydrogen atom was a big step forward. The concept of stationary states provided a means of understanding both the stability of atoms and the quantum jumps that lead to discrete spectra. And Bohr's ability to derive the Balmer formula for the hydrogen spectrum indicated that he was on the right track. Yet, as we have seen, the Bohr model was not successful for any neutral atom other than hydrogen.

Now it's Schrödinger's turn. Is Schrödinger's theory of quantum mechanics better at explaining atomic structure than other models? The answer, as you can probably anticipate, is a decisive yes. This chapter is an overview of how quantum mechanics finally provides us with an understanding of atomic structure and atomic properties.

42.1 The Hydrogen Atom: Angular Momentum and Energy

Let's begin with a quantum-mechanical model of the hydrogen atom. FIGURE 42.1 on the next page shows an electron at distance r from a proton. The proton is much more massive than the electron, so we will assume that the proton remains at rest at the origin.

As you learned in Chapter 41, the problem-solving procedure in quantum mechanics consists of two basic steps:

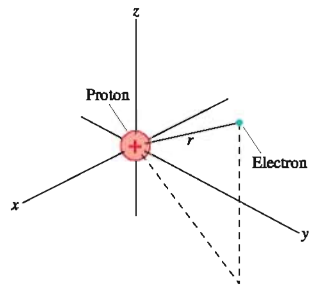
1. Specify a potential-energy function.
2. Solve the Schrödinger equation to find the wave functions, allowed energy levels, and other quantum properties.

The first step is easy. The proton and electron are charged particles with $q = \pm e$, so the potential energy of a hydrogen atom as a function of the electron distance r is

$$U(r) = -\frac{1}{4\pi\epsilon_0}\frac{e^2}{r} \tag{42.1}$$

The difficulty arises with the second step. The Schrödinger equation of Chapter 41 was for one-dimensional problems. Atoms are three-dimensional, and the three-dimensional Schrödinger equation turns out to be a partial differential equation whose solution is outside the scope of this textbook. Consequently, we'll present results without derivation or proof. The good news is that you have learned enough quantum mechanics to interpret and use the results.

FIGURE 42.1 The electron in a hydrogen atom is distance r from the proton.



Stationary States of Hydrogen

In one dimension, energy quantization appeared as a consequence of *boundary conditions* on the wave function. That is, only for certain discrete energies, characterized by the quantum number n, did solutions to the Schrödinger equation satisfy the boundary conditions. In three dimensions, the wave function must satisfy *three* different boundary conditions. Consequently, solutions to the three-dimensional Schrödinger equation have *three* quantum numbers and *three* quantized parameters.

Solutions to the Schrödinger equation for the hydrogen atom potential energy exist only if three conditions are satisfied:

1. The atom's energy must be one of the values

$$E_n = -\frac{1}{n^2}\left(\frac{1}{4\pi\epsilon_0}\frac{e^2}{2a_B}\right) = -\frac{13.60\text{ eV}}{n^2} \qquad n = 1, 2, 3, \ldots \tag{42.2}$$

where $a_B = 4\pi\epsilon_0\hbar^2/me^2 = 0.0529$ nm is the Bohr radius. The integer n is called the **principal quantum number.** These energies are the same as those in the Bohr hydrogen atom.

2. The angular momentum L of the electron's orbit must be one of the values

$$L = \sqrt{l(l+1)}\hbar \qquad l = 0, 1, 2, 3, \ldots, n-1 \tag{42.3}$$

The integer l is called the **orbital quantum number.**

3. The z-component of the angular momentum L_z must be one of the values

$$L_z = m\hbar \qquad m = -l, -l+1, \ldots, 0, \ldots, l-1, l \tag{42.4}$$

The integer m is called the **magnetic quantum number.**

In other words, each stationary state of the hydrogen atom is identified by a triplet of quantum numbers (n, l, m). Each quantum number is associated with a physical property of the atom.

NOTE ▶ The energy of the stationary state depends only on the principal quantum number n, not on l or m. ◀

EXAMPLE 42.1 Listing quantum numbers

List all possible states of a hydrogen atom that have energy $E = -3.40$ eV.

SOLVE Energy depends only on the principal quantum number n. States with $E = -3.40$ eV have

$$n = \sqrt{\frac{-13.60\text{ eV}}{-3.40\text{ eV}}} = 2$$

An atom with principal quantum number $n = 2$ could have either $l = 0$ or $l = 1$, but $l \geq 2$ is ruled out. If $l = 0$, the only possible value for the magnetic quantum number m is $m = 0$. If $l = 1$, then the atom could have $m = -1$, $m = 0$, or $m = +1$. Thus the possible quantum numbers are

n	l	m
2	0	0
2	1	1
2	1	0
2	1	−1

These four states all have the same energy.

TABLE 42.1 Symbols used to represent quantum number l

l	Symbol
0	s
1	p
2	d
3	f

Hydrogen turns out to be unique. For all other elements, the allowed energies depend on both n and l (but not m). Consequently, it is useful to label the stationary states by their values of n and l. The lowercase letters shown in Table 42.1 are customarily used to represent the various values of quantum number l. These symbols come from spectroscopic notation used in prequantum-mechanics days, when some spectral lines were classified as sharp, others as principal, and so on.

Using these symbols, we call the ground state of the hydrogen atom, with $n = 1$ and $l = 0$, the 1s state. The 3d state has $n = 3$, $l = 2$. In Example 42.1, we found one 2s state (with $l = 0$) and three 2p states (with $l = 1$), all with the same energy.

Angular Momentum Is Quantized

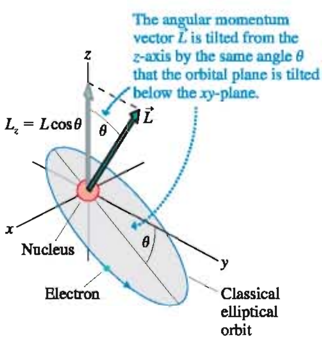


FIGURE 42.2 The angular momentum of an elliptical orbit.

If the hydrogen atom were classical, the electron's orbit, like that of a planet in the solar system, would be an ellipse. Furthermore, the orbit need not lie in the xy-plane. **FIGURE 42.2** shows a classical orbit tilted at angle θ below the xy-plane.

We introduced the angular momentum vector $\vec{L}$ in Chapter 12. It will be useful to call $\vec{L}$ the *orbital* angular momentum in order to distinguish it later from the *spin* angular momentum. Figure 42.2 reminds you that the vector $\vec{L}$ is perpendicular to the plane of the electron's orbit. The angular momentum vector has a z-component $L_z = L\cos\theta$ along the z-axis.

Classically, L and L_z can have any values. Not so in quantum mechanics. Quantum conditions 2 and 3 tell us that **the electron's orbital angular momentum is quantized.** The magnitude of the orbital angular momentum must be one of the discrete values

$$L = \sqrt{l(l+1)}\hbar = 0, \sqrt{2}\hbar, \sqrt{6}\hbar, \sqrt{12}\hbar, \ldots$$

where l is an integer. Simultaneously, the z-component L_z must have one of the values $L_z = m\hbar$, where m is an integer between $-l$ and l. No other values of L or L_z allow the wave function to satisfy the boundary conditions.

The quantization of angular momentum places restrictions on the shape and orientation of the electron's orbit. To see this, consider a hydrogen atom with orbital quantum number $l = 2$. In this state, the *magnitude* of the electron's angular momentum must be $L = \sqrt{6}\hbar = 2.45\hbar$. Furthermore, the angular momentum vector must point in a *direction* such that $L_z = m\hbar$, where m is one of only five integers in the range $-2 \leq m \leq 2$.

The combination of these two requirements allows $\vec{L}$ to point only in certain directions in space, as shown in **FIGURE 42.3** on the next page. This is a rather unusual figure that requires a little thought to understand. Suppose $m = 0$ and thus $L_z = 0$. With no z-component, the angular momentum vector $\vec{L}$ must lie somewhere in the xy-plane. Furthermore, because the length of $\vec{L}$ is constrained to be $2.45\hbar$, the tip of $\vec{L}$ must lie somewhere on the circle labeled $m = 0$. These values of $\vec{L}$ correspond to classical orbits tipped into a vertical plane.

Similarly, $m = 2$ requires $\vec{L}$ to lie along the cone whose height is $2\hbar$ and whose side has length $2.45\hbar$. These values of $\vec{L}$ correspond to classical orbits tilted slightly

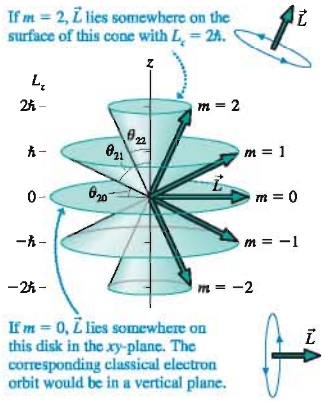
out of the xy-plane. Notice that **$\vec{L}$ cannot point directly along the z-axis.** The maximum possible value of L_z, when $m = l$, is $(L_z)_{max} = l\hbar$. But $l < \sqrt{l(l+1)}$, so $(L_z)_{max} < L$. The angular momentum vector *must* have either an x- or a y-component (or both). In other words, the corresponding classical orbit cannot lie in the xy-plane.

An angular momentum vector $\vec{L}$ tilted at angle θ from the z-axis corresponds to an orbit tilted at angle θ out of the xy-plane. The quantization of angular momentum restricts the orbital planes to only a few discrete angles. For quantum state (n, l, m), the angle of the angular momentum vector is

$$\theta_{lm} = \cos^{-1}\left(\frac{L_z}{L}\right) = \cos^{-1}\left(\frac{m\hbar}{\sqrt{l(l+1)}\hbar}\right) = \cos^{-1}\left(\frac{m}{\sqrt{l(l+1)}}\right) \quad (42.5)$$

Angles θ_{22}, θ_{21}, and θ_{20} are labeled in FIGURE 42.3. Orbital planes at other angles are not allowed because they don't satisfy the quantization conditions for angular momentum.

FIGURE 42.3 The five possible orientations of the angular momentum vector for $l = 2$. The angular momentum vectors all have length $L = \sqrt{6}\hbar = 2.45\hbar$.



EXAMPLE 42.2 The angle of the angular momentum vector

What is the angle between $\vec{L}$ and the z-axis for a hydrogen atom in the stationary state $(n, l, m) = (4, 2, 1)$?

SOLVE The angle θ_{21} is labeled in Figure 42.3. The state (4, 2, 1) has $l = 2$ and $m = 1$, thus

$$\theta_{21} = \cos^{-1}\left(\frac{1}{\sqrt{6}}\right) = 65.9°$$

ASSESS This quantum state corresponds to a classical orbit tilted 65.9° away from the xy-plane.

NOTE ▶ The ground state of hydrogen, with $l = 0$, has *no* angular momentum. A classical particle cannot orbit unless it has angular momentum, but apparently a quantum particle does not have this requirement. We will examine this issue in the next section. ◀

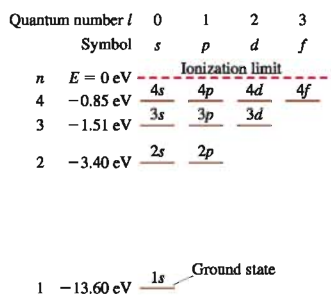
Energy Levels of the Hydrogen Atom

The energy of the hydrogen atom is quantized. Only those energies given by Equation 42.2 allow the wave function to satisfy the boundary conditions. The allowed energies of hydrogen depend only on the principal quantum number n, but for other atoms the energies will depend on both n and l. In anticipation of using both quantum numbers, FIGURE 42.4 is an *energy-level diagram* for the hydrogen atom in which the rows are labeled by n and the columns by l. The left column contains all of the $l = 0$ s states, the next column is the $l = 1$ p states, and so on.

Because the quantum condition of Equation 42.3 requires $n > l$, the s states begin with $n = 1$, the p states begin with $n = 2$, and the d states with $n = 3$. That is, the lowest-energy d state is $3d$ because states with $n = 1$ or $n = 2$ cannot have $l = 2$. For hydrogen, where the energy levels do not depend on l, the energy-level diagram shows that the $3s$, $3p$, and $3d$ states have equal energy. Figure 42.4 shows only the first few energy levels for each value of l, but there really are an infinite number of levels, as $n \to \infty$, crowding together beneath $E = 0$. The dashed line at $E = 0$ is the atom's *ionization limit*, the energy of a hydrogen atom in which the electron has been moved infinitely far away to form an H^+ ion.

The lowest energy state, the $1s$ state with $E_1 = -13.60$ eV, is the *ground state* of hydrogen. The value $|E_1| = 13.60$ eV is the **ionization energy**, the *minimum* energy that would be needed to form a hydrogen ion by removing the electron from the ground state. All of the states with $n > 1$ are *excited states*.

FIGURE 42.4 Energy-level diagram for the hydrogen atom.



STOP TO THINK 42.1 What are the quantum numbers n and l for a hydrogen atom with $E = -(13.60/9)$ eV and $L = \sqrt{2}\hbar$?

The red color of this nebula is due to the emission of light from hydrogen atoms. The atoms are excited by intense ultraviolet light from the star in the center. They then emit red light ($\lambda = 656$ nm) in a $3 \rightarrow 2$ transition, part of the Balmer series of spectral lines emitted by hydrogen.

42.2 The Hydrogen Atom: Wave Functions and Probabilities

You learned in Chapter 41 that the probability of finding a particle in a small interval of width δx at the position x is given by

$$\text{Prob(in } \delta x \text{ at } x) = |\psi(x)|^2 \delta x = P(x)\,\delta x$$

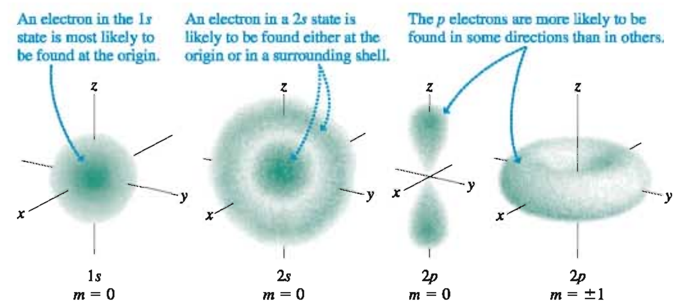
where $P(x) = |\psi(x)|^2$ is the probability density. This interpretation of $|\psi(x)|^2$ as a probability density lies at the heart of quantum mechanics. However, $P(x)$ was for a one-dimensional wave function. Because we're now looking at a three-dimensional atom, we need to consider the probability of finding a particle in a small *volume* of space δV at the position described by the three coordinates (x, y, z). This probability is

$$\text{Prob(in } \delta V \text{ at } x, y, z) = |\psi(x, y, z)|^2 \delta V \tag{42.6}$$

We can still interpret $|\psi(x, y, z)|^2$ as a probability density.

In one-dimensional quantum mechanics we could simply graph $P(x)$ versus x. Portraying the probability density of a three-dimensional wave function is more of a challenge. One way to do so, shown in **FIGURE 42.5**, is to use denser shading to indicate regions of larger probability density. That is, the amplitude of ψ is larger, and the electron is more likely to be found in regions where the shading is darker. These figures show the probability densities of the $1s$, $2s$, and $2p$ states of hydrogen. As you can see, the probability density in three dimensions creates what is often called an **electron cloud** around the nucleus.

FIGURE 42.5 The probability densities of the electron in the $1s$, $2s$, and $2p$ states of hydrogen.



These figures contain a lot of information. For example, notice how the p electrons have directional properties. These directional properties allow p electrons to "reach out" toward nearby atoms, forming molecular bonds. The quantum mechanics of bonding goes beyond what we can study in this text, but the electron-cloud pictures of the p electrons begin to suggest how bonds could form.

Radial Wave Functions

Figures such as Figure 42.5 are useful for "seeing" the electron clouds, but these figures are hard to use. Often, we would simply like to know the probability of finding the electron at a certain *distance* from the nucleus. That is, what is the probability that the electron is to be found within the small range of distances δr at the distance r?

It turns out that the solutions to the three-dimensional Schrödinger equation can be written in a form that focuses on the electron's radial distance r from the proton. The portion of the wave function that depends only on r is called the **radial wave function.** These functions, which depend on the quantum numbers n and l, are designated $R_{nl}(r)$. The first three radial wave functions are

$$\begin{aligned} R_{1s}(r) &= \frac{1}{\sqrt{\pi a_B^3}} e^{-r/a_B} \\ R_{2s}(r) &= \frac{1}{\sqrt{8\pi a_B^3}}\left(1 - \frac{r}{2a_B}\right)e^{-r/2a_B} \\ R_{2p}(r) &= \frac{1}{\sqrt{24\pi a_B^3}}\left(\frac{r}{2a_B}\right)e^{-r/2a_B} \end{aligned} \tag{42.7}$$

where a_B is the Bohr radius.

The radial wave functions may seem mysterious, because we haven't shown where they come from, but they are essentially the same as the one-dimensional wave functions $\psi(x)$ you learned to work with in Chapter 41. In fact, these radial wave functions are mathematically similar to the one-dimensional wave functions of the simple harmonic oscillator. One important difference, however, is that r ranges from 0 to ∞. For one-dimensional wave functions, x ranged from $-\infty$ to ∞.

FIGURE 42.6 shows the radial wave functions for the $1s$ and $2s$ states. Notice that the radial wave function is nonzero at $r = 0$, the position of the nucleus. This is surprising, but it is consistent with our observation in Figure 42.5 that the $1s$ and $2s$ electrons have a strong probability of being found at the origin.

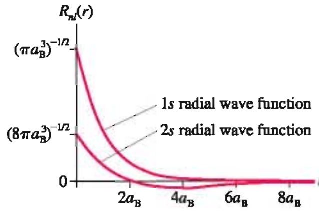


FIGURE 42.6 The $1s$ and $2s$ radial wave functions of hydrogen.

We can gain some understanding of the s-state wave functions by considering the angular momentum. A classical particle, for which $L = mvr$, can have $L = 0$ only if the radius of its orbit shrinks to zero. This is impossible for a classical particle, but zero angular momentum *is* achievable for quantum particles because the uncertainty principle prevents a quantum particle from being localized at a single point. The s-state wave functions of Figure 42.6, with their maximum values at $r = 0$, are the quantum analogs of a classical particle orbiting with $r = 0$.

Our purpose for introducing the radial wave functions was to determine the probability of finding the electron a certain *distance* from the nucleus. **FIGURE 42.7** shows a shell of radius r and thickness δr centered on the nucleus. The probability of finding the electron at distance r from the nucleus is equivalent to the probability that the electron is located somewhere within this shell. The volume of a thin shell is its surface area multiplied by its thickness δr. The surface area of a sphere is $4\pi r^2$, so the volume of this thin shell is

$$\delta V = 4\pi r^2 \delta r \tag{42.8}$$

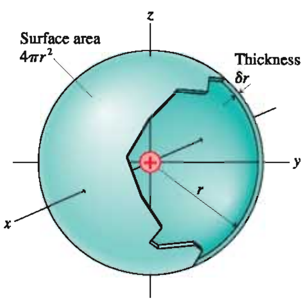

FIGURE 42.7 The radial probability density gives the probability of finding the electron in a spherical shell of thickness δr at radius r.

We will assert, without proof, that the probability of finding the electron within this shell is

$$\text{Prob(in } \delta r \text{ at } r) = |R_{nl}(r)|^2 \delta V = 4\pi r^2 |R_{nl}(r)|^2 \delta r = P_r(r)\,\delta r \tag{42.9}$$

where

$$P_r(r) = 4\pi r^2 |R_{nl}(r)|^2 \tag{42.10}$$

is called the **radial probability density** for the state nl.

The radial probability density tells us the relative likelihood of finding the electron at distance r from the nucleus. The volume factor $4\pi r^2$ reflects the fact that more space is available in a shell of larger r, and this additional space increases the probability of finding the electron at that distance.

The probability of finding the electron between r_{min} and r_{max} is

$$\text{Prob}(r_{min} \le r \le r_{max}) = \int_{r_{min}}^{r_{max}} P_r(r)\,dr = 4\pi \int_{r_{min}}^{r_{max}} r^2 |R_{nl}(r)|^2 dr \tag{42.11}$$

FIGURE 42.8 The radial probability densities for $n = 1, 2$, and 3.

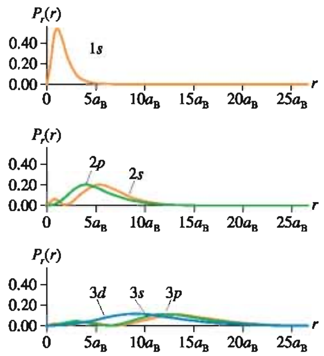

FIGURE 42.9 More circular orbits have larger angular momenta.

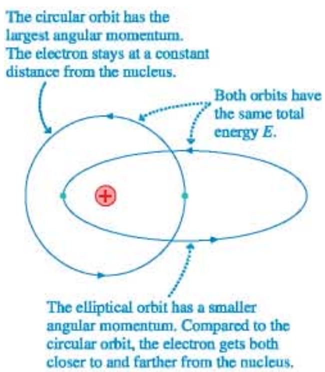

The electron must be *somewhere* between $r = 0$ and $r = \infty$, so the integral of $P_r(r)$ between 0 and ∞ must equal 1. This normalization condition was used to determine the constants in front of the radial wave functions of Equations 42.7.

FIGURE 42.8 shows the radial probability densities for the $n = 1, 2$, and 3 states of the hydrogen atom, all drawn to the same scale so that you can compare them to each other. The horizontal scale is in units of the Bohr radius a_B.

You can see that the $1s$, $2p$, and $3d$ states, with maxima at a_B, $4a_B$, and $9a_B$, respectively, are following the pattern $r_{peak} = n^2 a_B$. These are exactly the radii of the orbits in the Bohr hydrogen atom. There we simply bent a one-dimensional de Broglie wave into a circle of that radius. Now we have a three-dimensional wave function for which the electron is *most likely* to be this distance from the nucleus, although it *could* be found at other values of r. The physical situation is very different in quantum mechanics, but it is good to see that various aspects of the Bohr atom can be reproduced.

But why is it the $3d$ state that agrees with the Bohr atom rather than $3s$ or $3p$? All states with the same value of n form a collection of "orbits" having the same energy. In **FIGURE 42.9**, the state with $l = n - 1$ has the largest angular momentum of the group. Consequently, the maximum-l state corresponds to a circular classical orbit and matches the circular orbits of the Bohr atom. Notice that the radial probability densities for the $2p$ and $3d$ states have a single peak, corresponding to a classical orbit at a constant distance.

States with smaller l correspond to elliptical orbits. You can see in Figure 42.8 that the radial probability density of a $3s$ electron has a peak close to the nucleus. The $3s$ electron also has a good chance of being found *farther* from the nucleus than a $3d$ electron, suggesting an orbit that alternately swings in near the nucleus, then moves out past the circular orbit with the same energy. This distinction between circular and elliptical orbits will be important when we discuss the energy levels in multielectron atoms.

NOTE ▶ In quantum mechanics, nothing is really orbiting. However, the probability densities for the electron to be, or not to be, any given distance from the nucleus mimic certain aspects of classical orbits and provide a useful analogy. ◀

You can see in Figure 42.8 that the most likely distance from the nucleus of an $n = 1$ electron is approximately a_B. The distance of an $n = 2$ electron is most likely to be between about $3a_B$ and $7a_B$. An $n = 3$ electron is most likely to be found between about $8a_B$ and $15a_B$. In other words, the radial probability densities give the clear impression that each value of n has a fairly well-defined range of radii where the electron is most likely to be found. This is the basis of the **shell model** of the atom that is used in chemistry.

However, there's one significant puzzle. In Figure 42.5, the fuzzy sphere representing the $1s$ ground state is densest at the center, where the electron is most likely to be found. This maximum density at $r = 0$ agrees with the $1s$ radial wave function of Figure 42.6, which is a maximum at $r = 0$, but it seems to be in sharp disagreement with the $1s$ graph of Figure 42.8, which is *zero* at the nucleus and peaks at $r = a_B$.

Resolving this puzzle requires distinguishing between the probability density $|\psi(x, y, z)|^2$ and the *radial* probability density $P_r(r)$. The $1s$ wave function, and thus the $1s$ probability density, really does peak at the nucleus. But $|\psi(x, y, z)|^2$ is the probability of being in a small volume δV, such as a small box with sides δx, δy, and δz, whereas $P_r(r)$ is the probability of being in a spherical shell of thickness δr. Compared to $r = 0$, the probability density $|\psi(x, y, z)|^2$ is smaller at any *one* point having $r = a_B$. But the volume of *all* points with $r \approx a_B$ (i.e., the volume of the spherical shell at $r = a_B$) is so large that the radial probability density P_r peaks at this distance.

To use a mass analogy, consider a fuzzy ball that is densest at the center. Even though the density away from the center has decreased, a spherical shell of modest radius r can have *more total mass* than a small-radius spherical shell of the same thickness simply because it has so much more volume.

EXAMPLE 42.3 Maximum probability

Show that an electron in the 2*p* state is most likely to be found at $r = 4a_B$.

SOLVE We can use the 2*p* radial wave function from Equations 42.7 to write the radial probability density

$$P_r(r) = 4\pi r^2|R_{2p}(r)|^2 = 4\pi r^2\left[\frac{1}{\sqrt{24\pi a_B^3}}\left(\frac{r}{2a_B}\right)e^{-r/2a_B}\right]^2$$
$$= Cr^4e^{-r/a_B}$$

where $C = (24a_B^5)^{-1}$ is a constant. This expression for $P_r(r)$ was graphed in Figure 42.8.

The most probable value of r occurs at the point where the derivative of $P_r(r)$ is zero:

$$\frac{dP_r}{dr} = C(4r^3)(e^{-r/a_B}) + C(r^4)\left(\frac{-1}{a_B}e^{-r/a_B}\right)$$
$$= Cr^3\left(4 - \frac{r}{a_B}\right)e^{-r/a_B} = 0$$

This expression is zero only if $r = 4a_B$, so $P_r(r)$ is maximum at $r = 4a_B$. An electron in the 2*p* state is most likely to be found at this distance from the nucleus.

STOP TO THINK 42.2 How many maxima will there be in a graph of the radial probability density for the 4*s* state of hydrogen?

42.3 The Electron's Spin

Recall, from Chapter 33, that an electron orbiting a nucleus generates a microscopic *magnetic moment* $\vec{\mu}$. FIGURE 42.10 reminds you that a magnetic moment, like a compass needle, has north and south poles. Consequently, a magnetic moment in an external magnetic field experiences forces and torques. In the early 1920s, the German physicists Otto Stern and Walter Gerlach developed a technique to measure the magnetic moments of atoms. Their apparatus, shown in FIGURE 42.11, prepares an *atomic beam* by evaporating atoms out of a hole in an "oven." These atoms, traveling in a vacuum, pass through a *nonuniform* magnetic field. The field is stronger toward the top of the magnet, weaker toward the bottom.

FIGURE 42.10 An orbiting electron generates a magnetic moment.

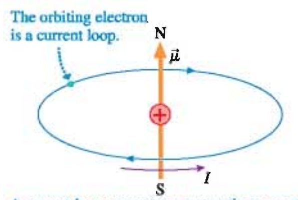

FIGURE 42.11 The Stern-Gerlach experiment.

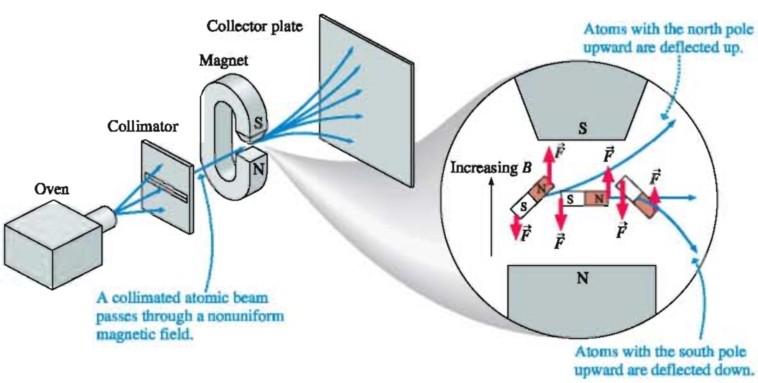

A magnetic moment experiences a *net force* in a nonuniform magnetic field because the field exerts forces of different strengths on the moment's north and south poles. An atom whose magnetic moment vector $\vec{\mu}$ is tilted upward ($\mu_z > 0$) has an upward force on its north pole that is larger than the downward force on its south pole. As the figure shows, this atom is deflected upward as it passes through the magnet. A

FIGURE 42.12 Distribution of the atoms on the collector plate.

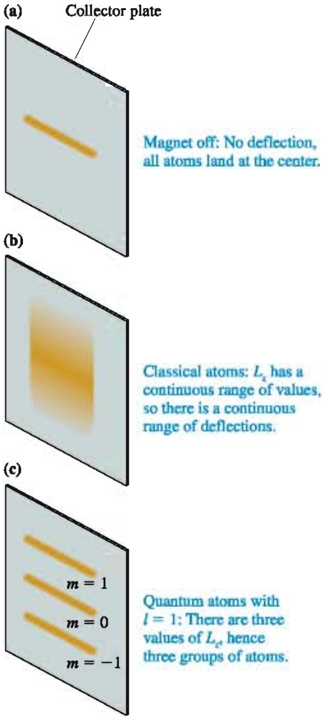

FIGURE 42.13 The outcome of the Stern-Gerlach experiment for hydrogen atoms.

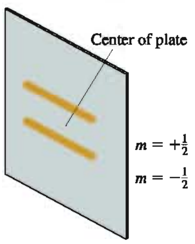


downward-tilted magnetic moment ($\mu_z < 0$) experiences a net downward force and is deflected downward. A magnetic moment perpendicular to the field ($\mu_z = 0$) feels no net force and passes through the magnet without deflection. In other words, an atom's deflection as it passes through the magnet is proportional to μ_z, the z-component of its magnetic moment.

It's not hard to show, although we will omit the proof, that an atom's magnetic moment is proportional to the electron's orbital angular momentum: $\vec{\mu} \propto \vec{L}$. Because the deflection of an atom depends on μ_z, measuring the deflections in a nonuniform field provides information about the L_z values of the atoms in the atomic beam. The measurements are made by allowing the atoms to stick on a collector plate at the end of the apparatus. After the experiment has been run for several hours, the collector plate is removed and examined to learn how the atoms are being deflected.

With the magnet off, the atoms pass through without deflection and land along a narrow line at the center, as shown in FIGURE 42.12a. If the orbiting electrons are classical particles, they should have a continuous range of angular momenta. Turning on the magnet should produce a continuous range of vertical deflections, and the distribution of atoms collected on the plate should look like FIGURE 42.12b. But if angular momentum is *quantized,* as Bohr had suggested several years earlier, the atoms should be deflected to discrete positions on the collector plate.

For example, an atom with $l = 1$ has three distinct values of L_z corresponding to quantum numbers $m = -1$, 0, and 1. This leads to a prediction of the three distinct groups of atoms shown in FIGURE 42.12c. There should always be an *odd* number of groups because there are $2l + 1$ values of L_z.

In 1927, with Schrödinger's quantum theory brand new, the Stern-Gerlach technique was used to measure the magnetic moment of hydrogen atoms. The ground state of hydrogen is $1s$, with $l = 0$, so the atoms should have *no* magnetic moment and there should be *no* deflection at all. Instead, the experiment produced the two-peaked distribution shown in FIGURE 42.13.

Because the hydrogen atoms were deflected, they *must* have a magnetic moment. But where does it come from if $L = 0$? Even stranger was the deflection into two groupings, rather than an odd number. The deflection is proportional to L_z, and $L_z = m\hbar$ where m ranges in integer steps from $-l$ to $+l$. The experimental results would make sense only if $l = \frac{1}{2}$, allowing m to take the two possible values $-\frac{1}{2}$ and $+\frac{1}{2}$. But according to Schrödinger's theory, the quantum numbers l and m must be integers.

An explanation for these observations was soon suggested, then confirmed: The electron has an *inherent* magnetic moment. After all, the electron has an inherent gravitational character, its mass m_e, and an inherent electric character, its charge $q_e = -e$. These are simply part of what an electron is. Thus it is plausible that an electron should also have an inherent magnetic character described by a built-in magnetic moment $\vec{\mu}_e$. A classical electron, if thought of as a little ball of charge, could spin on its axis as it orbits the nucleus. A spinning ball of charge would have a magnetic moment associated with its angular momentum. This inherent magnetic moment of the electron is what caused the unexpected deflection in the Stern-Gerlach experiment.

If the electron has an inherent magnetic moment, it must have an inherent angular momentum. This angular momentum is called the electron's **spin,** which is designated $\vec{S}$. The outcome of the Stern-Gerlach experiment tells us that the z-component of this spin angular momentum is

$$S_z = m_s\hbar \quad \text{where } m_s = +\tfrac{1}{2} \quad \text{or} \quad -\tfrac{1}{2} \tag{42.12}$$

The quantity m_s is called the **spin quantum number.**

The z-component of the spin angular momentum vector is determined by the electron's orientation. The $m_s = +\frac{1}{2}$ state, with $S_z = +\frac{1}{2}\hbar$, is called the **spin-up** state and the $m_s = -\frac{1}{2}$ state is called the **spin-down** state. It is convenient to picture a little angular momentum vector that can be drawn ↑ for an $m_s = +\frac{1}{2}$ state and ↓ for an $m_s = -\frac{1}{2}$ state. We will use this notation in the next section. Because the electron must

be either spin-up or spin-down, a hydrogen atom in the Stern-Gerlach experiment will be deflected either up or down. This causes the two groups of atoms seen in Figure 42.13. No atoms have $S_z = 0$, so there are no undeflected atoms in the center.

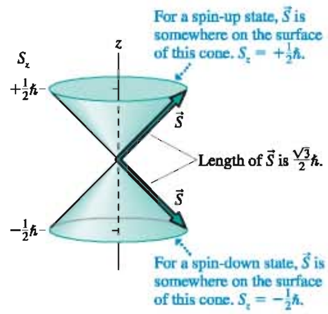
NOTE ▶ The atom has spin angular momentum *in addition* to any orbital angular momentum that the electrons may have. Only in s states, for which $L = 0$, can we see the effects of "pure spin." ◀

The spin angular momentum S is analogous to Equation 42.3 for L:

$$S = \sqrt{s(s+1)}\hbar = \frac{\sqrt{3}}{2}\hbar \tag{42.13}$$

where s is a quantum number with the single value $s = \frac{1}{2}$. S is the ***inherent*** angular momentum of the electron. Because of the single value of s, physicists usually say that the electron has "spin one-half." FIGURE 42.14, which should be compared to Figure 42.3, shows that the terms "spin up" and "spin down" refer to S_z, not the full spin angular momentum. As was the case with $\vec{L}$, it's not possible for $\vec{S}$ to point along the z-axis.

FIGURE 42.14 The spin angular momentum has two possible orientations.



NOTE ▶ The term "spin" must be used with caution. Although a classical charged particle could generate a magnetic moment by spinning, the electron most assuredly is *not* a classical particle. It is not spinning in any literal sense. It simply has an inherent magnetic moment, just as it has an inherent mass and charge, and that magnetic moment makes it look *as if* the electron is spinning. It is a convenient figure of speech, not a factual statement. **The electron has a spin, but it is not a spinning electron!** ◀

The electron's spin has significant implications for atomic structure. The solutions to the Schrödinger equation could be described by the three quantum numbers n, l, and m, but the Stern-Gerlach experiment implies that this is not a complete description of an atom. Knowing that a ground-state atom has quantum numbers $n = 1$, $l = 0$, and $m = 0$ is not sufficient to predict whether the atom will be deflected up or down in a nonuniform magnetic field. We need to add the spin quantum number m_s to make our description complete. (Strictly speaking, we also need to add the quantum number s, but it provides no additional information because its value never changes.) So we really need *four* quantum numbers (n, l, m, m_s) to characterize the stationary states of the atom. The spin orientation does not affect the atom's energy, so a ground-state electron in hydrogen could be in either the $(1, 0, 0, +\frac{1}{2})$ spin-up state or the $(1, 0, 0, -\frac{1}{2})$ spin-down state.

The fact that s has the single value $s = \frac{1}{2}$ has other interesting implications. The correspondence principle tells us that a quantum particle begins to "act classical" in the limit of large quantum numbers. But s cannot become large! **The electron's spin is an intrinsic quantum property of the electron that has *no* classical counterpart.**

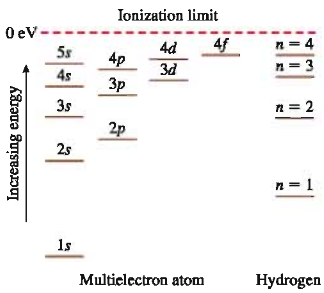
STOP TO THINK 42.3 Can the spin angular momentum vector lie in the xy-plane? Why or why not?

42.4 Multielectron Atoms

The Schrödinger-equation solution for the hydrogen atom matches the experimental evidence, but so did the Bohr hydrogen atom. The real test of Schrödinger's theory is how well it works for multielectron atoms. A neutral multielectron atom consists of Z electrons surrounding a nucleus with Z protons and charge $+Ze$. Z, the *atomic number*, is the order in which elements are listed in the periodic table. Hydrogen is $Z = 1$, helium $Z = 2$, lithium $Z = 3$, and so on.

The potential-energy function of a multielectron atom is that of Z electrons interacting with the nucleus *and* Z electrons interacting *with each other.* The electron-electron interaction makes the atomic-structure problem more difficult than the solar-system problem, and it proved to be the downfall of the simple Bohr model. The planets in the solar system do exert attractive gravitational forces on each other, but their masses are so much less than that of the sun that these planet-planet forces are insignificant for all but the most precise calculations. Not so in an atom. The electron charge is the same as the proton charge, so the electron-electron repulsion is just as important to atomic structure as is the electron-nucleus attraction.

FIGURE 42.15 An energy-level diagram for electrons in a multielectron atom.



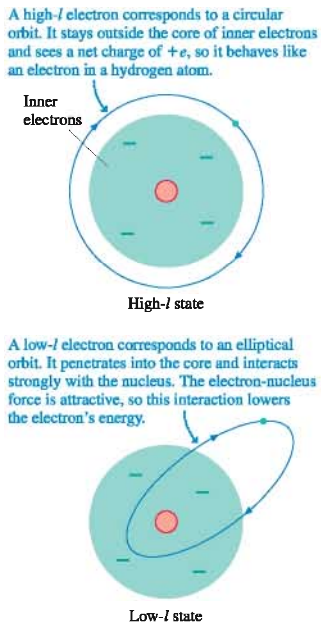
The potential energy due to electron-electron interactions fluctuates rapidly in value as the electrons move and the distances between them change. Rather than treat this interaction in detail, we can reasonably consider each electron to be moving in an *average* potential due to all the other electrons. That is, electron i has potential energy

$$U(r_i) = -\frac{Ze^2}{4\pi\epsilon_0 r_i} + U_{\text{elec}}(r_i) \tag{42.14}$$

where the first term is the electron's interaction with the Z protons in the nucleus and U_{elec} is the average potential energy due to all the other electrons. Because each electron is treated independently of the other electrons, this approach is called the **independent particle approximation,** or IPA. This approximation allows the Schrödinger equation for the atom to be broken into Z separate equations, one for each electron.

A major consequence of the IPA is that **each electron can be described by a wave function having the same four quantum numbers n, l, m, and m_s used to describe the single electron of hydrogen.** Because m and m_s do not affect the energy, we can still refer to electrons by their n and l quantum numbers, using the same labeling scheme that we used for hydrogen.

FIGURE 42.16 High-l and low-l orbitals in a multielectron atom.



A major difference, however, is that the energy of an electron in a multielectron atom depends on both n *and* l. Whereas the $2s$ and $2p$ states in hydrogen had the same energy, their energies are different in a multielectron atom. The difference arises from the electron-electron interactions that do not exist in a single-electron hydrogen atom.

FIGURE 42.15 shows an energy-level diagram for the electrons in a multielectron atom. For comparison, the hydrogen-atom energies are shown on the right edge of the figure. The comparison is quite interesting. States in a multielectron atom that have small values of l are significantly lower in energy than the corresponding state in hydrogen. For each n, the energy increases as l increases until the maximum-l state has an energy very nearly that of the same n in hydrogen. Can we understand this pattern?

Indeed we can. Recall that states of lower l correspond to elliptical classical orbits and the highest-l state corresponds to a circular orbit. Except for the smallest values of n, an electron in a circular orbit spends most of its time *outside* the electron cloud of the remaining electrons. This is illustrated in **FIGURE 42.16.** The outer electron is orbiting a ball of charge consisting of Z protons and $(Z-1)$ electrons. This ball of charge has *net* charge $q_{\text{net}} = +e$, so the outer electron "thinks" it is orbiting a proton. An electron in a maximum-l state is nearly indistinguishable from an electron in the hydrogen atom; thus its energy is very nearly that of hydrogen.

The low-l states correspond to elliptical orbits. A low-l electron penetrates in very close to the nucleus, which is no longer shielded by the other electrons. The electron's interaction with the Z protons in the nucleus is much stronger than the interaction it would have with the single proton in a hydrogen nucleus. This strong interaction *lowers* its energy in comparison to the same state in hydrogen.

As we noted earlier, a quantum electron does not really orbit. Even so, the probability density of a $3s$ electron has in-close peaks that are missing in the probability density of a $3d$ electron, as you should confirm by looking back at Figure 42.8. Thus a low-l electron really does have a likelihood of being at small r, where its interaction with the Z protons is strong, whereas a high-l electron is most likely to be farther from the nucleus.

The Pauli Exclusion Principle

By definition, the ground state of a quantum system is the state of lowest energy. What is the ground state of an atom having Z electrons and Z protons? Because the $1s$ state is the lowest energy state in the independent particle approximation, it seems that the ground state should be one in which all Z electrons are in the $1s$ state. However, this idea is not consistent with the experimental evidence.

In 1925, the young Austrian physicist Wolfgang Pauli hypothesized that no two electrons in a quantum system can be in the same quantum state. That is, **no two electrons can have exactly the same set of quantum numbers (n, l, n, m_s).** If one electron is present in a state, it *excludes* all others. This statement, which is called the **Pauli exclusion principle,** turns out to be an extremely profound statement about the nature of matter.

The exclusion principle is not applicable to hydrogen, which has only a single electron. But in helium, with $Z = 2$ electrons, we must make sure that the two electrons are in different quantum states. This is not difficult. For a $1s$ state, with $l = 0$, the only possible value of the magnetic quantum number is $m = 0$. But there are *two* possible values of m_s, namely $+\frac{1}{2}$ and $-\frac{1}{2}$. If a first electron is in the spin-up $1s$ state $(1, 0, 0, +\frac{1}{2})$, a second $1s$ electron can still be added to the atom as long as it is in the spin-down state $(1, 0, 0, -\frac{1}{2})$. This is shown schematically in FIGURE 42.17a, where the dots represent electrons on the rungs of the "energy ladder" and the arrows represent spin-up or spin-down.

The Pauli exclusion principle does not prevent both electrons of helium from being in the $1s$ state as long as they have opposite values of m_s, so we predict this to be the ground state. A list of an atom's occupied energy levels is called its **electron configuration.** The electron configuration of the helium ground state is written $1s^2$, where the superscript 2 indicates two electrons in the $1s$ energy level. An excited state of the helium atom might be the electron configuration $1s2s$. This state is shown in FIGURE 42.17b. Here, because the two electrons have different values of n, there is no restriction on their values of m_s.

The states $(1, 0, 0, +\frac{1}{2})$ and $(1, 0, 0, -\frac{1}{2})$ are the only two states with $n = 1$. The ground state of helium has one electron in each of these states, so all the possible $n = 1$ states are filled. Consequently, the electron configuration $1s^2$ is called a **closed shell.** Because the two electron magnetic moments point in opposite directions, we can predict that helium has *no* net magnetic moment and will be undeflected in a Stern-Gerlach apparatus. This prediction is confirmed by experiment.

The next element, lithium, has $Z = 3$ electrons. The first two electrons can go into $1s$ states, with opposite values of m_s, but what about the third electron? The $1s^2$ shell is closed, and there are no additional quantum states having $n = 1$. The only option for the third electron is the next energy state, $n = 2$. The $2s$ and $2p$ states had equal energies in the hydrogen atom, but they do *not* in a multielectron atom. As Figure 42.15 showed, a lower-l state has lower energy than a higher-l state with the same n. The $2s$ state of lithium is lower in energy than $2p$, so lithium's third ground-state electron will be $2s$. This requires $l = 0$ and $m = 0$ for the third electron, but the value of m_s is not relevant because there is only a single electron in $2s$. FIGURE 42.18a shows the electron configuration with the $2s$ electron being spin-up, but it could equally well be spin-down. The electron configuration for the lithium ground state is written $1s^22s$. This indicates two $1s$ electrons and a single $2s$ electron.

FIGURE 42.19a shows the probability density of electrons in the $1s^22s$ ground state of lithium. You can see the $2s$ electron shell surrounding the inner $1s^2$ core. For comparison, FIGURE 42.19b shows the *first excited state* of lithium, in which the $2s$ electron has been excited to the $2p$ energy level. This forms the $1s^22p$ configuration, also shown in FIGURE 42.18b.

FIGURE 42.17 The ground state and the first excited state of helium.

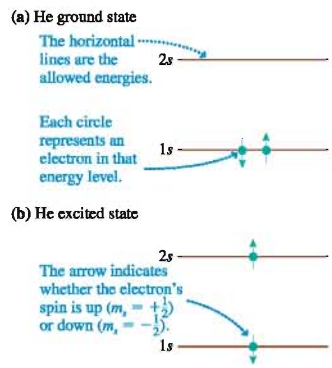


FIGURE 42.18 The ground state and the first excited state of lithium.

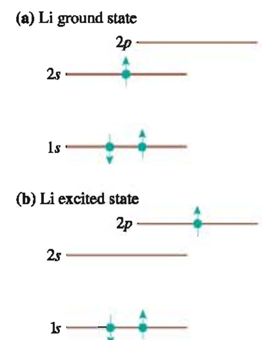

FIGURE 42.19 Electron clouds for the lithium electron configurations $1s^22s$ and $1s^22p$.

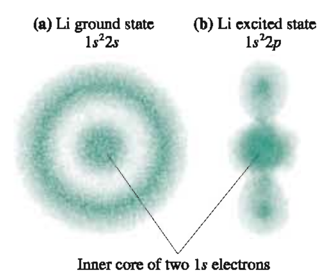


The Schrödinger equation accurately predicts the energies of the $1s^22s$ and the $1s^22p$ configurations of lithium, but the Schrödinger equation does not tell us which states the electrons actually occupy. The electron spin and the Pauli exclusion principle were the final pieces of the puzzle. Once these were added to Schrödinger's theory, the initial phase of quantum mechanics was complete. Physicists finally had a successful theory for understanding the structure of atoms.

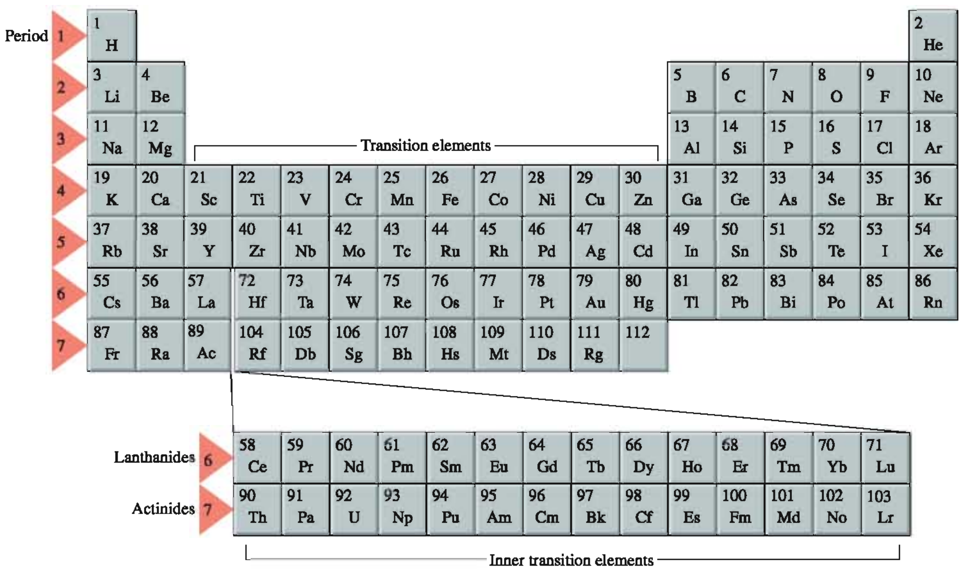
42.5 The Periodic Table of the Elements

The 19th century was a time when scientists were discovering new elements and studying their chemical properties. Several chemists in the 1860s began to point out the regular recurrence of chemical properties. For example, there are obvious similarities among the alkali metals lithium, sodium, potassium, and cesium. But attempts at organization were hampered by the fact that many elements had yet to be discovered.

The Russian chemist Dmitri Mendeléev was the first to propose, in 1867, a *periodic* arrangement of the elements. He did so by explicitly pointing out "gaps" where, according to his hypothesis, undiscovered elements should exist. He could then predict the expected properties of the missing elements. The subsequent discovery of these elements verified Mendeléev's organizational scheme, which came to be known as the *periodic table of the elements.*

FIGURE 42.20 shows a modern periodic table. A larger version is printed in Appendix B. The significance of the periodic table to a physicist is the implication that there is a basic regularity or periodicity to the *structure* of atoms. Any successful theory of the atom needs to explain *why* the periodic table looks the way it does.

FIGURE 42.20 The modern periodic table of the elements, showing the atomic number Z of each.



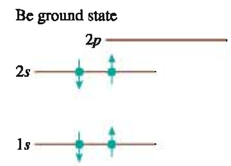
The First Two Rows

Quantum mechanics successfully explains the structure of the periodic table. We need three basic ideas to see how this works:

1. The energy levels of an atom are found by solving the Schrödinger equation for multielectron atoms. Figure 42.15, a very important figure for understanding the periodic table, showed that the energy depends on the quantum numbers n and l.
2. For each value l of the orbital quantum number, there are $2l + 1$ possible values of the magnetic quantum number m and, for each of these, two possible values of the spin quantum number m_s. Consequently, each energy *level* in Figure 42.15 is actually $2(2l + 1)$ different *states*. Each of these states has the same energy.
3. The ground state of the atom is the lowest-energy electron configuration that is consistent with the Pauli exclusion principle.

We used these ideas in the last section to look at the elements helium ($Z = 2$) and lithium ($Z = 3$). Four-electron beryllium ($Z = 4$) comes next. The first two electrons go into $1s$ states, forming a closed shell, and the third goes into $2s$. There is room in the $2s$ level for a second electron as long as its spin is opposite that of the first $2s$ electron. Thus the third and fourth electrons occupy states $(2, 0, 0, +\frac{1}{2})$ and $(2, 0, 0, -\frac{1}{2})$. These are the only two possible $2s$ states. All the states with the same values of n and l are called a **subshell,** so the fourth electron closes the $2s$ subshell. (The outer two electrons are called a subshell, rather than a shell, because they complete only the $2s$ possibilities. There are still spaces for $2p$ electrons.) The ground state of beryllium, shown in FIGURE 42.21, is $1s^22s^2$.

FIGURE 42.21 The ground state of beryllium ($Z = 4$).



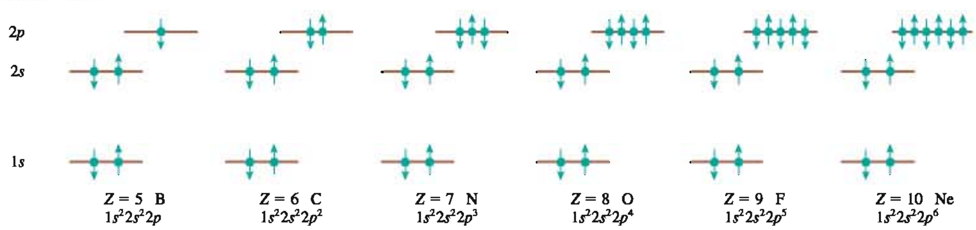
These principles can continue to be applied as we work our way through the elements. There are $2l + 1$ values of m associated with each value of l, and each of these can have $m_s = \pm\frac{1}{2}$. This gives, altogether, $2(2l + 1)$ distinct quantum states in each nl subshell. Table 42.2 lists the number of states in each subshell.

TABLE 42.2 Number of states in each subshell of an atom

Subshell	l	Number of states
s	0	2
p	1	6
d	2	10
f	3	14

Boron ($1s^22s^22p$) opens the $2p$ subshell. The remaining possible $2p$ states are filled as we continue across the second row of the periodic table. These elements are shown in FIGURE 42.22. With neon ($1s^22s^22p^6$), which has six $2p$ electrons, the $n = 2$ shell is complete, and we have another closed shell. The second row of the periodic table is eight elements wide because of the two $2s$ electrons *plus* the six $2p$ electrons needed to fill the $n = 2$ shell.

FIGURE 42.22 Filling the $2p$ subshell with the elements boron through neon.



Elements with $Z > 10$

The third row of the periodic table is similar to the second. The two $3s$ states are filled in sodium and magnesium. The two columns on the left of the periodic table represent the two electrons that can go into an s subshell. Then the six $3p$ states are filled, one by one, in aluminum through argon. The six columns on the right represent the six electrons of the p subshell. Argon ($Z = 18$, $1s^22s^22p^63s^23p^6$) is another inert gas, although this may seem surprising because the $3d$ subshell is still open.

The fourth row is where the periodic table begins to get complicated. You might expect the closure of the $3p$ subshell in argon to be followed, starting with potassium ($Z = 19$), by filling the $3d$ subshell. But if you look back at Figure 42.15, where the energies of the different nl states are shown, you will see that the $3d$ state is slightly *higher* in energy than the $4s$ state. Because the ground state is the *lowest energy state* consistent with the Pauli exclusion principle, potassium finds it more favorable to fill a $4s$ state than to fill a $3d$ state. Thus the ground state configuration of potassium is $1s^22s^22p^63s^23p^64s$ rather than the expected $1s^22s^22p^63s^23p^63d$.

At this point, we begin to see a competition between increasing n and decreasing l. The highly elliptical characteristic of the $4s$ state brings part of its orbit in so close to the nucleus that its energy is less than that of the more circular $3d$ state. The $4p$ state, though, reverts to the "expected" pattern. We find that

$$E_{4s} < E_{3d} < E_{4p}$$

so the states across the fourth row are filled in the order $4s$, then $3d$, and finally $4p$.

Because there had been no previous d states, the $3d$ subshell "splits open" the periodic table to form the 10-element-wide group of *transition elements*. Most commonly occurring metals are transition elements, and their metallic properties are determined by their partially filled d subshell. The $3d$ subshell closes with zinc, at $Z = 30$, then the next six elements fill the $4p$ subshell up to krypton, at $Z = 36$.

Things get even more complex starting in the sixth row, but the ideas are familiar. The $l = 3$ subshell (f electrons) becomes a possibility with $n = 4$, but it turns out that the $5s$, $5p$, and $6s$ states are all lower in energy than $4f$. Not until barium ($Z = 56$) fills the $6s$ subshell (and lanthanum ($Z = 57$) adds a $5d$ electron) is it energetically favorable to add a $4f$ electron. Immediately after lanthanum you have to switch down to the *lanthanides* at the bottom of the table. The lanthanides fill in the $4f$ states.

The $4f$ subshell is complete with $Z = 71$ lutetium. Then $Z = 72$ hafnium through $Z = 80$ mercury complete the transition-element $5d$ subshell, followed by the $6p$ subshell in the six elements thallium through radon at the end of the sixth row. Radon, the last inert gas, has $Z = 86$ electrons and the ground-state configuration

$$1s^22s^22p^63s^23p^64s^23d^{10}4p^65s^24d^{10}5p^66s^24f^{14}5d^{10}6p^6$$

This is frightening to behold, but we can now understand it!

EXAMPLE 42.4 The ground state of arsenic

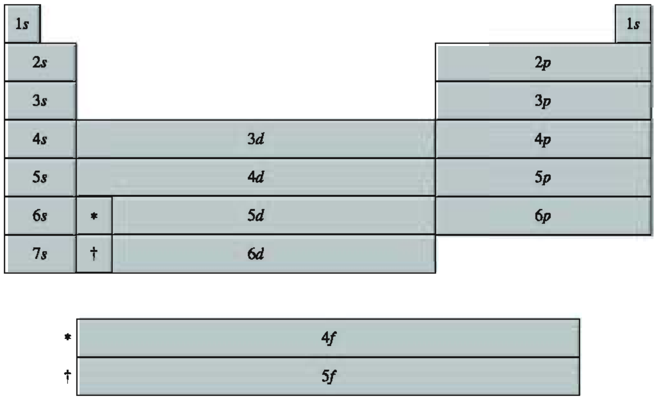
Predict the ground-state electron configuration of arsenic.

SOLVE The periodic table shows that arsenic (As) has $Z = 33$, so we must identify the states of 33 electrons. Arsenic is in the fourth row, following the first group of transition elements. Argon ($Z = 18$) filled the $3p$ subshell, then calcium ($Z = 20$) filled the $4s$ subshell. The next 10 elements, through zinc ($Z = 30$), filled the $3d$ subshell. The $4p$ subshell starts filling with gallium ($Z = 31$), and arsenic is the third element in this group, so it will have three $4p$ electrons. Thus the ground-state configuration of arsenic is

$$1s^22s^22p^63s^23p^64s^23d^{10}4p^3$$

The entire periodic table is well explained by quantum mechanics. FIGURE 42.23 summarizes the results, showing the subshells as they are filled. It is especially important to note the significance of the electron's spin. Although the introduction of the electron's spin and magnetic moment may have seemed obscure and unnecessary, we now find that the spin quantum number m_s is absolutely essential for understanding the periodic table.

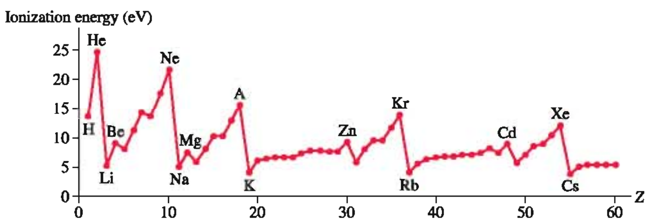
FIGURE 42.23 Summary of the order in which subshells are filled in the periodic table.



Ionization Energies

Ionization energy is the minimum energy needed to remove a ground-state electron from an atom and leave a positive ion behind. The ionization energy of hydrogen is 13.60 eV because the ground-state energy is $E_1 = -13.60$ eV. **FIGURE 42.24** shows the ionization energies of the first 60 elements in the periodic table.

FIGURE 42.24 Ionization energies of the elements up to $Z = 60$.



The ionization energy is different for each element, but there's a clear pattern to the values. Ionization energies are ≈5 eV for the alkali metals, on the left edge of the periodic table, then increase steadily to ≥15 eV for the inert gases before plunging back to ≈5 eV. Can the quantum theory of atoms explain this recurring pattern in the ionization energies?

Indeed it can. The inert-gas elements (helium, neon, argon, . . .) in the right column of the periodic table have *closed shells*. A closed shell is a very stable structure, and that is why these elements are chemically nonreactive (i.e., inert). It takes a large amount of energy to pull an electron out of a stable closed shell; thus the inert gases have the largest ionization energies.

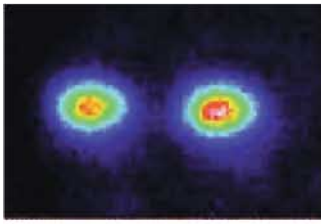
The alkali metals, in the left column of the periodic table, have a single *s*-electron outside a closed shell. This electron is easily disrupted, which is why these elements are highly reactive and have the lowest ionization energies. Between the edges of the periodic table are elements such as beryllium ($1s^22s^2$) with a closed 2*s* subshell. You can see in Figure 42.24 that the closed subshell gives beryllium a larger ionization energy than its neighbors lithium ($1s^22s$) or boron ($1s^22s^22p$). However, a closed subshell is not nearly as tightly bound as a closed shell, so the ionization energy of beryllium is much less than that of helium or neon.

All in all, you can see that the basic idea of shells and subshells, which follows from the Schrödinger-equation energy levels and the Pauli principle, provides a good understanding of the recurring features in the ionization energies.

STOP TO THINK 42.4 Is the electron configuration $1s^22s^22p^43s$ a ground-state configuration or an excited-state configuration?

a. Ground-state
b. Excited-state
c. It's not possible to tell without knowing which element it is.

42.6 Excited States and Spectra



The dots of light are being emitted by two beryllium ions held in a device called an ion trap. Each ion, which is excited by an invisible ultraviolet laser, emits about 10^6 visible-light photons per second.

The periodic table organizes information about the *ground states* of the elements. These states are chemically most important because most atoms spend most of the time in their ground states. All the chemical ideas of valence, bonding, reactivity, and so on are consequences of these ground-state atomic structures. But the periodic table does not tell us anything about the excited states of atoms. It is the excited states that hold the key to understanding atomic spectra, and that is the topic to which we turn next.

Sodium ($Z = 11$) is a multielectron atom that we will use as a prototypical atom. The ground-state electron configuration of sodium is $1s^22s^22p^63s$. The first 10 electrons completely fill the $n = 1$ and $n = 2$ shells, creating a *neon core,* while the $3s$ electron is a valence electron. It is customary to represent this configuration as [Ne]$3s$ or, more simply, as just $3s$.

18.2 ActivPhysics ONLINE

The excited states of sodium are produced by raising the valence electron to a higher energy level. The electrons in the neon core are unchanged. Thus the excited states can be labeled [Ne]nl or, more simply, just nl. Figure 42.25 is an energy-level diagram showing the ground state and some of the excited states of sodium. Notice that the $1s$, $2s$, and $2p$ states of the neon core are not shown on the diagram. These states are filled and unchanging, so only the states available to the valence electron are shown.

FIGURE 42.25 The [Ne]$3s$ ground state of the sodium atom and some of the excited states.

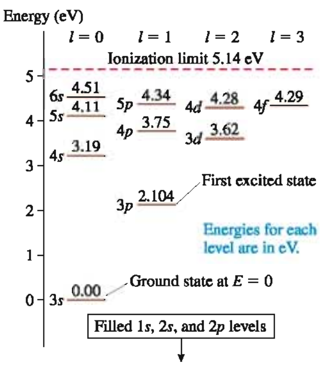


FIGURE 42.25 has a new feature: The zero of energy has been shifted to the ground state. As we have discovered many times, the zero of energy can be located where it is most convenient. When we solved the Schrödinger equation, it was most convenient to let zero energy represent the energy of an electron infinitely far away. But for analyzing spectra it is more convenient to let the ground state have $E = 0$. With this choice, the excited-state energies tell us how far each state is above the ground state. The ionization limit now occurs at the value of the atom's ionization energy, which is 5.14 eV for sodium.

The first energy level above $3s$ is $3p$, so the *first excited state* of sodium is $1s^22s^22p^63p$, written as [Ne]$3p$ or, more simply, $3p$. The valence electron is excited while the core electrons are unchanged. This state is followed, in order of increasing energy, by [Ne]$4s$, [Ne]$3d$, and [Ne]$4p$. Notice that the order of excited states is exactly the same order ($3p$–$4s$–$3d$–$4p$) that explained the fourth row of the periodic table.

Other atoms with a single valence electron have energy-level diagrams similar to that of sodium. Things get more complicated when there is more than one valence electron, so we'll defer those details to more advanced courses. The point to remember is that quantum mechanics provides the correct framework for classifying and understanding the many interactions that take place within an atom. You can *utilize* the information shown on an energy-level diagram without having to understand precisely *why* each level is where it is.

Excitation by Absorption

Left to itself, an atom will be in its lowest-energy ground state. How does an atom get into an excited state? The process of getting it there is called **excitation,** and there are

two basic mechanisms: absorption and collision. We'll begin by looking at excitation by absorption.

One of the postulates of the basic Bohr model is that an atom can jump from one stationary state, of energy E_1, to a higher-energy state E_2 by absorbing a photon of frequency

$$f = \frac{\Delta E_{atom}}{h} = \frac{E_2 - E_1}{h} \tag{42.15}$$

Because we are interested in spectra, it is more useful to write Equation 42.15 in terms of the wavelength:

$$\lambda = \frac{c}{f} = \frac{hc}{\Delta E_{atom}} = \frac{1240 \text{ eV nm}}{\Delta E \text{ (in eV)}} \tag{42.16}$$

The final expression, which uses the value $hc = 1240$ eV nm, gives the wavelength in nanometers *if* ΔE_{atom} is in electron volts.

Bohr's idea of quantum jumps remains an integral part of our interpretation of the results of quantum mechanics. By absorbing a photon, an atom jumps from its ground state to one of its excited states. However, a careful analysis of how the electrons in an atom interact with a light wave shows that not every conceivable transition can occur. The **allowed transitions** must satisfy one or more **selection rules.**

The only selection rule that will concern us says that a transition (either absorption or emission) from a state in which the valence electron has orbital quantum number l_1 to another with orbital quantum number l_2 is allowed only if

$$\Delta l = |l_2 - l_1| = 1 \quad \text{(selection rule for emission and absorption)} \tag{42.17}$$

That is, the electron's orbital quantum number must change by exactly 1. Thus an atom in an s state ($l = 0$) can absorb a photon and be excited to a p state ($l = 1$) but *not* to another s state or to a d state. An atom in a p state ($l = 1$) can emit a photon by dropping to a lower-energy s state *or* to a lower-energy d state but not to another p state.

EXAMPLE 42.5 Absorption in hydrogen

What is the longest wavelength in the absorption spectrum of hydrogen? What is the transition?

SOLVE The longest wavelength corresponds to the smallest energy change ΔE_{atom}. Because the atom starts from the $1s$ ground state, the smallest energy change occurs for absorption to the first $n = 2$ excited state. The energy change is

$$\Delta E_{atom} = E_2 - E_1 = \frac{-13.6 \text{ eV}}{2^2} - \frac{-13.6 \text{ eV}}{1^2} = 10.2 \text{ eV}$$

The wavelength of this transition is

$$\lambda = \frac{1240 \text{ eV nm}}{10.2 \text{ eV}} = 122 \text{ nm}$$

This is an ultraviolet wavelength. Because of the selection rule, the transition is $1s \rightarrow 2p$, not $1s \rightarrow 2s$.

EXAMPLE 42.6 Absorption in sodium

What is the longest wavelength in the absorption spectrum of sodium? What is the transition?

SOLVE The sodium ground state is [Ne]$3s$. The lowest excited state is the $3p$ state. $3s \rightarrow 3p$ is an allowed transition ($\Delta l = 1$), so this will be the longest wavelength. You can see from the data in Figure 42.25 that $\Delta E_{atom} = 2.104$ eV for this transition. The corresponding wavelength is

$$\lambda = \frac{1240 \text{ eV nm}}{2.104 \text{ eV}} = 589 \text{ nm}$$

ASSESS This wavelength (yellow color) is a prominent feature in the spectrum of sodium. Because the ground state has $l = 0$, absorption *must* be to a p state. The s states and d states of sodium cannot be excited by absorption.

Collisional Excitation

An electron traveling with a speed of 1.0×10^6 m/s has a kinetic energy of 2.85 eV. If this electron collides with a ground-state sodium atom, a portion of its energy can be used to excite the atom to its $3p$ state. This process is called **collisional excitation** of the atom.

Collisional excitation differs from excitation by absorption in one very fundamental way. In absorption, the photon disappears. Consequently, *all* of the photon's energy must be transferred to the atom. Conservation of energy requires $E_{\text{photon}} = \Delta E_{\text{atom}}$. In contrast, the electron is still present after collisional excitation and can carry away some kinetic energy. That is, the electron does *not* have to transfer its entire energy to the atom. If the electron has an incident kinetic energy of 2.85 eV, it could transfer 2.10 eV to the sodium atom, thereby exciting it to the $3p$ state, and still depart the collision with a speed of 5.1×10^5 m/s and an energy of 0.75 eV.

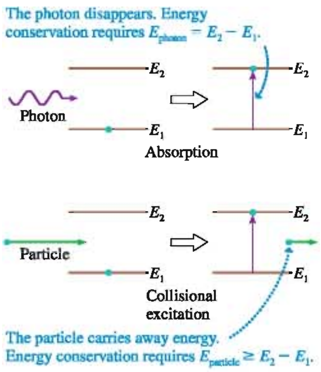

FIGURE 42.26 Excitation by photon absorption and electron collision.

To excite the atom, the incident energy of the electron (or any other matter particle) merely has to *exceed* ΔE_{atom}. That is $E_{\text{particle}} \geq \Delta E_{\text{atom}}$. There's a threshold energy for exciting the atom, but no upper limit. It is all a matter of energy conservation. **FIGURE 42.26** shows the idea graphically.

Collisional excitation by electrons is the predominant method of excitation in electrical discharges such as fluorescent lights, street lights, and neon signs. A gas is placed in a tube at reduced pressure ($\approx$1 mm of Hg), then a fairly high voltage ($\approx$1000 V) between electrodes at the ends of the tube causes the gas to ionize, creating a current in which both ions and electrons are charge carriers. The mean free path of electrons between collisions is large enough for the electrons to gain several eV of kinetic energy as they accelerate in the electric field. This energy is then transferred to the gas atoms upon collision. The process does not work at atmospheric pressure because the mean free path between collisions is too short for the electrons to gain enough kinetic energy to excite the atoms.

NOTE ▶ In contrast to photon absorption, there are no selection rules for collisional excitation. Any state can be excited if the colliding particle has sufficient energy. ◀

EXAMPLE 42.7 Excitation of hydrogen

Can an electron traveling at 2.0×10^6 m/s cause a hydrogen atom to emit the prominent red spectral line ($\lambda = 656$ nm) in the Balmer series?

MODEL The electron must have sufficient energy to excite the upper state of the transition.

SOLVE The electron's energy is $E_{\text{elec}} = \frac{1}{2}mv^2 = 11.4$ eV. This is significantly larger than the 1.89 eV energy of a photon with wavelength 656 nm, but don't confuse the energy of the photon with the energy of the excitation. The red spectral line in the Balmer series is emitted by an $n = 3$ to $n = 2$ quantum jump with $\Delta E_{\text{atom}} = 1.89$ eV. But to cause this emission, the electron must excite an atom from its *ground state,* with $n = 1$, up to the $n = 3$ level. The necessary excitation energy is

$$\Delta E_{\text{atom}} = E_3 - E_1 = (-1.51\text{ eV}) - (-13.60\text{ eV})$$
$$= 12.09\text{ eV}$$

The electron does *not* have sufficient energy to excite the atom to the state from which the emission would occur.

Emission Spectra

The absorption of light is an important process, but it is the emission of light that really gets our attention. The overwhelming bulk of sensory information that we perceive comes to us in the form of light. The recognition and appreciation of light and color have formed the basis of aesthetics and art since the days of prehistory. With the small exception of cosmic rays, all of our knowledge about the cosmos comes to us in the form of light and other electromagnetic waves emitted in various processes.

The discovery of discrete emission spectra helped bring down classical physics, and it was the understanding of discrete emission spectra that provided the first major triumph of quantum mechanics. Emission spectra are more than just scientific curiosi-

ties. Many of today's artificial light sources, from fluorescent lights to LEDs to lasers, are applications of emission spectra.

Understanding emission hinges on the three ideas shown in FIGURE 42.27. Once we have determined the energy levels of an atom, by solving the Schrödinger equation, we can immediately predict its emission spectrum. Conversely, we can use the measured emission spectrum to determine an atom's energy levels.

As an example, FIGURE 42.28a shows some of the transitions and wavelengths observed in the emission spectrum of sodium. This diagram makes the point that each wavelength represents a quantum jump between two well-defined energy levels. Notice that the selection rule $\Delta l = 1$ is being obeyed in the sodium spectrum. The $5p$ levels can undergo quantum jumps to $3s$, $4s$, or $3d$ but *not* to $3p$ or $4p$.

FIGURE 42.28b shows the emission spectrum of sodium as it would be recorded in a spectrometer. (Many of the lines seen in this spectrum start from higher excited states that are not seen in the rather limited energy-level diagram of Figure 42.28a.) By comparing the spectrum to the energy-level diagram, you can recognize that the spectral lines at 589 nm, 330 nm, 286 nm, and 268 nm form a *series* of lines due to all the possible $np \rightarrow 3s$ transitions. They are the dominant features in the sodium spectrum.

The most obvious visual feature of sodium emission is its bright yellow color, produced by the emission wavelength of 589 nm. This is the basis of the *flame test* used in chemistry to test for sodium: A sample is held in a Bunsen burner, and a bright yellow glow indicates the presence of sodium. The 589 nm emission is also prominent in the pinkish-yellow glow of the common sodium-vapor street lights. These operate by creating an electrical discharge in sodium vapor. Most sodium-vapor lights use high-pressure lamps to increase their light output. The high pressure, however, causes the formation of Na_2 molecules, and these molecules emit the pinkish portion of the light.

Some cities close to astronomical observatories use low-pressure sodium lights, and these emit the distinctive yellow 589 nm light of sodium. The glow of city lights is a severe problem for astronomers, but the very specific 589 nm emission from sodium is easily removed with a *sodium filter.* The light from the telescope is passed through a container of sodium vapor, and the sodium atoms *absorb* only the unwanted 589 nm photons without disturbing any other wavelengths! However, this cute trick does not work for the other wavelengths emitted by high-pressure sodium lamps or light from other sources.

FIGURE 42.27 Generation of an emission spectrum.

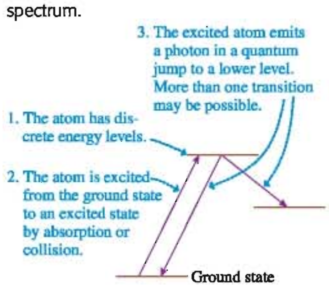

FIGURE 42.28 The emission spectrum of sodium.

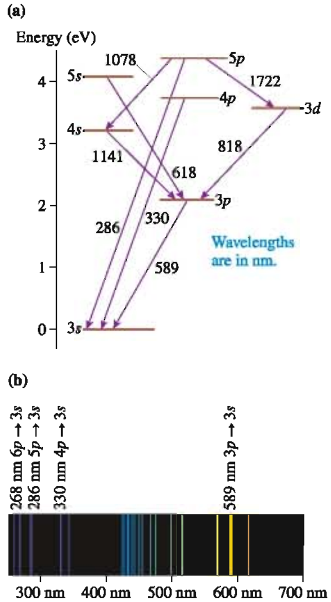


Color in Solids

It is worth concluding this section with a few remarks about color in solids. Whether it is the intense multihued colors of a stained glass window, the bright colors of flowers or paint, or the deep luminescent red of a ruby, most of the colors we perceive in our lives come from solids rather than free atoms. The basic principles are the same, but the details are different for solids.

An excited atom in a gas has little choice but to give up its energy by emitting a photon. Its only other option, which is rare for gas atoms, is to collide with another atom and transfer its energy into the kinetic energy of recoil. But the atoms in a solid are in intimate contact with each other at all times. Although an excited atom in a solid has the option of emitting a photon, it is often more likely that the energy will be converted, via interactions with neighboring atoms, to the thermal energy of the solid. A process in which an atom is de-excited without radiating is called a **nonradiative transition.**

This is what happens in pigments, such as those in paints, plants, and dyes. Pigment molecules absorb certain wavelengths of light but not other wavelengths. The energy-level structure of a molecule is complex, so the absorption consists of "bands" of wavelengths rather than discrete spectral lines. But instead of re-radiating the energy by photon emission, as a free atom would, the pigment molecules undergo nonradiative transitions and convert the energy into increased thermal energy. That is why darker objects get hotter in the sun than lighter objects.

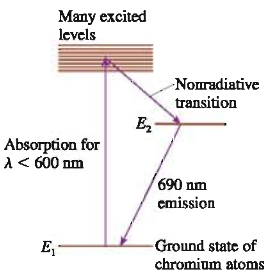
The colors in a stained-glass window are due to the selective absorption of light.

When light falls on an object, it can be either absorbed or reflected. If *all* wavelengths are reflected, the object is perceived as white. Any wavelengths absorbed by the pigments are removed from the reflected light. A pigment with blue-absorbing properties converts the energy of blue-wavelength photons into thermal energy, but photons of other wavelengths are reflected without change. A blue-absorbing pigment reflects the red and yellow wavelengths, causing the object to be perceived as the color orange!

Some solids, though, are a little different. The color of many minerals and crystals is due to so-called ***impurity atoms*** embedded in them. For example, the gemstone ruby is a very simple and common crystal of aluminum oxide, called corundum, that happens to have chromium atoms present at the concentration of about one part in a thousand. Pure corundum is transparent, so all of a ruby's color comes from these chromium impurity atoms.

FIGURE 42.29 shows what happens when ruby is illuminated by white light. The chromium atoms have a group of excited states that absorb all wavelengths shorter than about 600 nm—that is, everything except orange and red. Unlike the pigments in red glass, which convert all the absorbed energy into thermal energy, the chromium atoms dissipate only a small amount of heat as they undergo a nonradiative transition to another excited state. From there they emit a photon with $\lambda = hc/(E_2 - E_1) \approx 690$ nm (dark red color) as they jump back to the ground state.

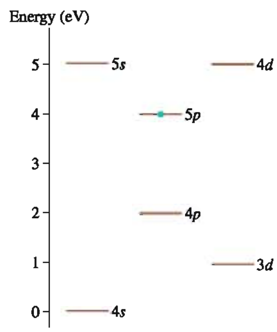
FIGURE 42.29 Absorption and emission in a crystal of ruby.



The net effect is that short-wavelength photons, rather than being completely absorbed, are *re-radiated* as longer-wavelength photons. This is why rubies sparkle and have such intense color, whereas red glass is a dull red color. The color of other minerals and gems is due to different impurity atoms, but the principle is the same.

STOP TO THINK 42.5 In this hypothetical atom, what is the photon energy E_{photon} of the longest-wavelength photons emitted by atoms in the $5p$ state?

a. 1.0 eV
b. 2.0 eV
c. 3.0 eV
d. 4.0 eV



42.7 Lifetimes of Excited States

Excitation of an atom, by either absorption or collision, leaves it in an excited state. From there it jumps back to a lower energy level by emitting a photon. How long does this process take? There are actually two questions here. First, how long does an atom remain in an excited state before undergoing a quantum jump to a lower state? Second, how long does the transition last as the quantum jump is occurring?

Our best understanding of the quantum physics of atoms is that quantum jumps are instantaneous. The absorption or emission of a photon is an all-or-nothing event, so there is not a time when a photon is "half emitted." The prediction that quantum jumps are instantaneous has troubled many physicists, but careful experimental tests have never revealed any evidence that the jump itself takes a measurable amount of time.

The time spent in the excited state, waiting to make a quantum jump, is another story. FIGURE 42.30 shows experimental data for the length of time that doubly charged xenon ions Xe^{++} spend in a certain excited state. In this experiment, a pulse of electrons was used to excite the atoms to the excited state. The number of excited-state atoms was then monitored by detecting the photons emitted—one-by-one!—as the excited atoms jumped back to the ground state. The number of photons emitted at time t is directly proportional to the number of excited-state atoms present at time t. As the figure shows, the number of atoms in the excited state decreases *exponentially* with time, and virtually all have decayed within 25 ms of their creation.

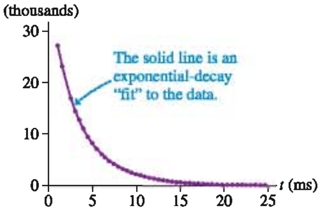


FIGURE 42.30 Experimental data for the photon emission rate from an excited state in Xe^{++}.

Figure 42.30 has two important implications. First, atoms spend time in the excited state before undergoing a quantum jump back to a lower state. Second, the length of time spent in the excited state is not a constant value but varies from atom to atom. If every excited xenon ion lived for 5 ms in the excited state, then we would detect *no* photons for 5 ms, a big burst right at 5 ms as they all decay, then no photons after that. Instead, the data tell us that there is a *range* of times spent in the excited state. Some undergo a quantum jump and emit a photon after 1 ms, others after 5 ms or 10 ms, and a few wait as long as 20 or 25 ms.

Consider an experiment in which N_0 excited atoms are created at time $t = 0$. As the curve in Figure 42.30 shows, the number of excited atoms remaining at time t is well described by the exponential function

$$N_{exc} = N_0 e^{-t/\tau} \tag{42.18}$$

where τ is the point in time at which $e^{-1} = 0.368 = 36.8\%$ of the original atoms are left. Thus 63.2% of the atoms, nearly two-thirds, have emitted a photon and jumped to the lower state by time $t = \tau$. The interval of time τ is called the **lifetime** of the excited state. From Figure 42.30 we can deduce that the lifetime of this state in Xe^{++} is ≈ 4 ms because that is the point in time at which the curve has decayed to 36.8% of its initial value.

This lifetime in Xe^{++} is abnormally long, which is why the state was studied. More typical excited-state lifetimes are a few nanoseconds. Table 42.3 gives some measured values of excited-state lifetimes. Whatever the value of τ, the number of excited-state atoms decreases exponentially. Why is this?

TABLE 42.3 Some excited-state lifetimes

Atom	State	Lifetime (ns)
Hydrogen	$2p$	1.6
Sodium	$3p$	17
Neon	$3p$	20
Potassium	$4p$	26

The Decay Equation

Quantum mechanics is about probabilities. We cannot say exactly where the electron is located, but we can use quantum mechanics to calculate the *probability* that the electron is located in a small interval Δx at position x. Similarly, we cannot say exactly when an excited electron will undergo a quantum jump and emit a photon. However, we can use quantum mechanics to find the *probability* that the electron will undergo a quantum jump during a small time interval Δt at time t.

Let us assume that the probability of an excited atom emitting a photon during time interval Δt is *independent* of how long the atom has been waiting in the excited state. For example, a newly excited atom may have a 10% probability of emitting a photon within the 1 ns interval from 0 ns to 1 ns. If it survives until $t = 7$ ns, our assumption is that it still has a 10% probability of emitting a photon during the 1 ns interval from 7 ns to 8 ns.

This assumption, which can be justified with a detailed analysis, is similar to flipping coins. The probability of a head on your first flip is 50%. If you flip seven heads in a row, the probability of a head on your eighth flip is still 50%. It is *unlikely* that you will flip seven heads in a row, but doing so does not influence the eighth flip. Likewise, it may be *unlikely* for an excited atom to live for 7 ns, but doing so does not affect its probability of emitting a photon during the next 1 ns.

If Δt is small, the probability of photon emission during time interval Δt is directly proportional to Δt. That is, if the emission probability in 1 ns is 1%, it will be 2% in 2 ns and 0.5% in 0.5 ns. (This logic fails if Δt gets too big. If the probability is 70% in

20 ns, we can *not* say that the probability would be 140% in 40 ns because a probability > 1 is meaningless.) We will be interested in the limit $\Delta t \to dt$, so the concept is valid and we can write

$$\text{Prob(emission in } \Delta t \text{ at time } t) = r\Delta t \tag{42.19}$$

where r is called the **decay rate** because the number of excited atoms decays with time. It is a probability *per second,* with units of s^{-1}, and thus is a rate. For example, if an atom has a 5% probability of emitting a photon during a 2 ns interval, its decay rate is

$$r = \frac{P}{\Delta t} = \frac{0.05}{2\text{ ns}} = 0.025\text{ ns}^{-1} = 2.5 \times 10^{7}\text{ s}^{-1}$$

NOTE ► Equation 42.19 is directly analogous to Prob(found in Δx at x) $= P\Delta x$, where P, which had units of m^{-1}, was the probability density. ◄

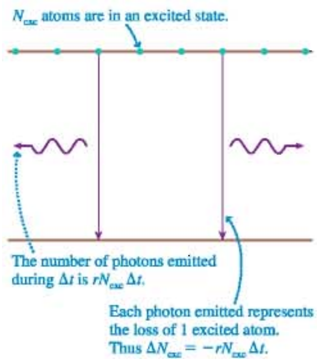

FIGURE 42.31 The number of atoms that emit photons during Δt is directly proportional to the number of excited atoms.

FIGURE 42.31 shows N_{exc} atoms in an excited state. During a small time interval Δt, the number of these atoms that we expect to undergo a quantum jump and emit a photon is N_{exc} multiplied by the probability of decay. That is,

$$\begin{aligned}\text{number of photons in } \Delta t \text{ at time } t &= N_{exc} \times \text{Prob(emission in } \Delta t \text{ at } t) \\ &= rN_{exc}\Delta t\end{aligned} \tag{42.20}$$

Now the *change* in N_{exc} is the *negative* of Equation 42.20. For example, suppose 1000 excited atoms are present at time t and each has a 5% probability of emitting a photon in the next 1 ns. On average, the number of photons emitted during the next 1 ns will be $1000 \times 0.05 = 50$. Consequently, the number of excited atoms changes by $\Delta N_{exc} = -50$, with the minus sign indicating a decrease.

Thus the *change* in the number of atoms in the excited state is

$$\Delta N_{exc}(\text{in } \Delta t \text{ at } t) = -N_{exc} \times \text{Prob(decay in } \Delta t \text{ at } t) = -rN_{exc}\Delta t \tag{42.21}$$

Now let $\Delta t \to dt$. Then $\Delta N_{exc} \to dN_{exc}$ and Equation 42.21 becomes

$$\frac{dN_{exc}}{dt} = -rN_{exc} \tag{42.22}$$

Equation 42.22 is a *rate equation* because it describes the *rate* at which the excited-state population changes. If r is large, the population will decay at a rapid rate and will have a short lifetime. Conversely, a small value of r implies that the population will decay slowly and will live a long time.

The rate equation is a differential equation, but we solved a similar equation for *RC* circuits in Chapter 32. First, we rewrite Equation 42.22 as

$$\frac{dN_{exc}}{N_{exc}} = -r\,dt$$

Then we integrate both sides from $t = 0$, when the initial excited-state population is N_0, to an arbitrary time t when the population is N_{exc}. That is,

$$\int_{N_0}^{N_{exc}} \frac{dN_{exc}}{N_{exc}} = -r\int_0^t dt \tag{42.23}$$

Both are well-known integrals, giving

$$\ln N_{exc}\Big|_{N_0}^{N_{exc}} = \ln N_{exc} - \ln N_0 = \ln\left(\frac{N_{exc}}{N_0}\right) = -rt$$

We can solve for the number of excited atoms at time t by taking the exponential of both sides, then multiplying by N_0. Doing so gives

$$N_{exc} = N_0 e^{-rt} \tag{42.24}$$

Notice that $N_{exc} = N_0$ at $t = 0$, as expected. Equation 42.24, the *decay equation,* shows that the excited-state population decays exponentially with time, as we saw in the experimental data of Figure 42.30.

It will be more convenient to write Equation 42.24 as

$$N_{exc} = N_0 e^{-t/\tau} \tag{42.25}$$

where

$$\tau = \frac{1}{r} = \text{the } \textit{lifetime} \text{ of the excited state} \tag{42.26}$$

This is the definition of the lifetime we used in Equation 42.18 to describe the experimental results. The lifetime is the inverse of the decay rate r.

EXAMPLE 42.8 The lifetime of an excited state in mercury

The mercury atom has two valence electrons. One is always in the $6s$ state, the other is in a state with quantum numbers n and l. One of the excited states in mercury is the state designated $6s6p$. The decay rate of this state is $7.7 \times 10^8\ \text{s}^{-1}$.

a. What is the lifetime of this state?
b. If 1.0×10^{10} mercury atoms are created in the $6s6p$ state at $t = 0$, how many photons will be emitted during the first 1.0ns?

SOLVE a. The lifetime is

$$\tau = \frac{1}{r} = \frac{1}{7.7 \times 10^8\ \text{s}^{-1}} = 1.3 \times 10^{-9}\ \text{s} = 1.3\ \text{ns}$$

b. If there are $N_0 = 10^{10}$ excited atoms at $t = 0$, the number still remaining at $t = 1.0$ ns is

$$N_{exc} = N_0 e^{-t/\tau} = (1.0 \times 10^{10}) e^{-(1.0\ \text{ns})/(1.3\ \text{ns})} = 4.63 \times 10^9$$

This result implies that 5.37×10^9 atoms undergo quantum jumps during the first 1.0 ns. Each of these atoms emits one photon, so the number of photons emitted during the first 1.0 ns is 5.37×10^9.

The decay rates r for excited states can be calculated in quantum mechanics and compared to experimentally measured lifetimes of excited states. The agreement is very good, thus providing another validation of the quantum-mechanical description of atoms.

STOP TO THINK 42.6 An equal number of excited A atoms and excited B atoms are created at $t = 0$. The decay rate of B atoms is twice that of A atoms: $r_B = 2r_A$. At $t = \tau_A$ (i.e., after one lifetime of A atoms has elapsed), the ratio N_B/N_A of the number of excited B atoms to the number of excited A atoms is

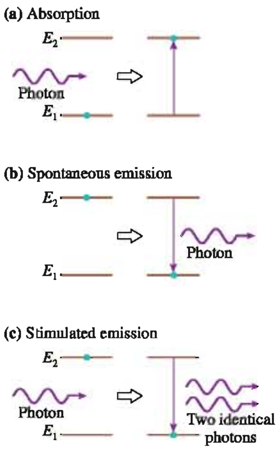
a. >2 b. 2 c. 1 d. $\frac{1}{2}$ e. $<\frac{1}{2}$

42.8 Stimulated Emission and Lasers

We have seen that an atom can jump from a lower-energy level E_1 to a higher-energy level E_2 by absorbing a photon. FIGURE 42.32a on the next page illustrates the basic absorption process, with a photon of frequency $f = \Delta E_{atom}/h$ disappearing as the atom jumps from level 1 to level 2. Once in level 2, as shown in FIGURE 42.32b, the atom can emit a photon of the same frequency as it jumps back to level 1. This transition is called **spontaneous emission.** ActivPhysics ONLINE 18.3

In 1917, four years after Bohr's proposal of stationary states in atoms but still prior to de Broglie and Schrödinger, Einstein was puzzled by how quantized atoms reach thermodynamic equilibrium in the presence of electromagnetic radiation. Einstein found that absorption and spontaneous emission were not sufficient to allow a

FIGURE 42.32 Three types of radiative transitions.



collection of atoms to reach thermodynamic equilibrium. To resolve this difficulty, Einstein proposed a third mechanism for the interaction of atoms with light.

The left half of FIGURE 42.32c shows a photon with frequency $f = \Delta E_{\text{atom}}/h$ approaching an *excited* atom. If a photon can induce the $1 \rightarrow 2$ transition of absorption, then Einstein proposed that it should also be able to induce a $2 \rightarrow 1$ transition. In a sense, this transition is a *reverse absorption*. But to undergo a reverse absorption, the atom must *emit* a photon of frequency $f = \Delta E_{\text{atom}}/h$. The end result, as seen in the right half of Figure 42.32c, is an atom in level 1 plus *two* photons! Because the first photon induced the atom to emit the second photon, this process is called **stimulated emission.**

Stimulated emission occurs only if the first photon's frequency exactly matches the $E_2 - E_1$ energy difference of the atom. This is precisely the same condition that absorption has to satisfy. More interesting, the emitted photon is *identical* to the incident photon. This means that as the two photons leave the atom they have exactly the same frequency and wavelength, are traveling in exactly the same direction, and are exactly in phase with each other. In other words, **stimulated emission produces a second photon that is an exact clone of the first.**

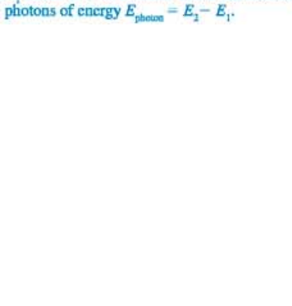
Stimulated emission is of no importance in most practical situations. Atoms typically spend only a few nanoseconds in an excited state before undergoing spontaneous emission, so the atom would need to be in an extremely intense light wave for stimulated emission to occur prior to spontaneous emission. Ordinary light sources are not nearly intense enough for stimulated emission to be more than a minor effect; hence it was many years before Einstein's prediction was confirmed. No one had doubted Einstein because he had clearly demonstrated that stimulated emission was necessary to make the energy equations balance, but it seemed no more important than would pennies to a millionaire balancing her checkbook. At least, that is, until 1960, when a revolutionary invention appeared that made explicit use of stimulated emission: the laser.

Lasers

The word **laser** is an acronym for light amplification by the stimulated emission of radiation. The first laser, a ruby laser, was demonstrated in 1960, and several other kinds of lasers appeared within a few months. The driving force behind much of the research was the American physicist Charles Townes. Townes was awarded the Nobel prize in 1964 for the invention of the maser, an earlier device using microwaves, and his theoretical work leading to the laser.

Today, lasers do everything from being the light source in fiber-optic communications to measuring the distance to the moon and from playing your CD to performing delicate eye surgery. But what is a laser? Basically it is a device that produces a beam of highly *coherent* and essentially monochromatic (single-color) light as a result of stimulated emission. **Coherent** light is light in which all the electromagnetic waves have the same phase, direction, and amplitude. It is the coherence of a laser beam that allows it to be very tightly focused or to be rapidly modulated for communications.

FIGURE 42.33 Energy levels 1 and 2, with populations N_1 and N_2.



Let's take a brief look at how a laser works. FIGURE 42.33 represents a system of atoms that have a lower energy level E_1 and a higher energy level E_2. Suppose there are N_1 atoms in level 1 and N_2 atoms in level 2. Left to themselves, all the atoms would soon end up in level 1 because of the spontaneous emission $2 \rightarrow 1$. To prevent this, we can imagine that some type of excitation mechanism, perhaps an electrical discharge, is continuing to produce new excited atoms in level 2.

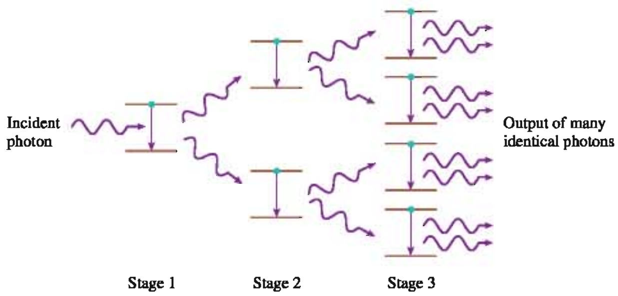
Let a photon of frequency $f = (E_2 - E_1)/h$ be incident on this group of atoms. Because it has the correct frequency, it could be absorbed by one of the atoms in level 1. Another possibility is that it could cause stimulated emission from one of the level 2 atoms. Ordinarily $N_2 \ll N_1$, so absorption events far outnumber stimulated emission events. Even if a few photons were generated by stimulated emission, they would quickly be absorbed by the vastly larger group of atoms in level 1.

But what if we could somehow arrange to place *every* atom in level 2, making $N_1 = 0$. Then the incident photon, upon encountering its first atom, will cause stimu-

lated emission. Where there was initially one photon of frequency f, now there are two. These will strike two additional excited-state atoms, again causing stimulated emission. Then there will be four photons. As FIGURE 42.34 shows, there will be a *chain reaction* of stimulated emission until all N_2 atoms emit a photon of frequency f.

Charles Townes.

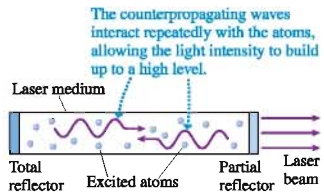
FIGURE 42.34 Stimulated emission creates a chain reaction of photon production in a population of excited atoms.



In stimulated emission, each emitted photon is *identical* to the incident photon. The chain reaction of Figure 42.34 will lead not just to N_2 photons of frequency f, but to N_2 *identical* photons, all traveling together in the same direction with the same phase. If N_2 is a large number, as would be the case in any practical device, the one initial photon will have been *amplified* into a gigantic coherent pulse of light! A collection of excited-state atoms is called an *optical amplifier*.

As FIGURE 42.35 shows, the stimulated emission is sustained by placing the *lasing medium*—the sample of atoms that emits the light—in an **optical cavity** consisting of two facing mirrors. One of the mirrors will be partially transmitting so that some of the light emerges as the *laser beam*.

FIGURE 42.35 Lasing takes place in an optical cavity.



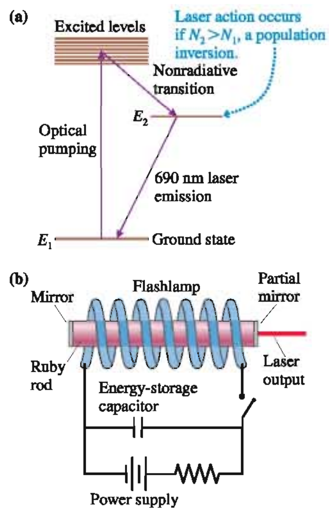
Although the chain reaction of Figure 42.34 illustrates the idea most clearly, it is not necessary for every atom to be in level 2 for amplification to occur. All that is needed is to have $N_2 > N_1$ so that stimulated emission exceeds absorption. Such a situation is called a **population inversion.** The process of obtaining a population inversion is called **pumping,** and we will look at two specific examples. Pumping is the technically difficult part of designing and building a laser because normal excitation mechanisms do not create population inversions. In fact, lasers would likely have been discovered accidentally long before 1960 if population inversions were easy to create.

The Ruby Laser

The first laser to be developed was a ruby laser. FIGURE 42.36a shows the energy-level structure of the chromium atoms that gives ruby its optical properties. Normally, the number of atoms in the ground-state level E_1 far exceeds the number of excited-state atoms with energy E_2. That is, $N_2 \ll N_1$. Under these circumstances 690 nm light is absorbed rather than amplified. But suppose that we could *rapidly* excite more than half the chromium atoms to level E_2. Then we would have a population inversion ($N_2 > N_1$) between levels E_1 and E_2.

This can be accomplished by *optically pumping* the ruby with a very intense pulse of white light from a *flashlamp*. A flashlamp is like a camera flash, only vastly more intense. In the basic arrangement of FIGURE 42.36b, a helical flashlamp is coiled around a ruby rod that has mirrors bonded to its end faces. The lamp is fired by discharging a high-voltage capacitor through it, creating a very intense light pulse lasting just a few microseconds. This intense light excites nearly all the chromium atoms from the ground state to the upper energy levels. From there, they quickly ($\approx 10^{-8}$ s) decay nonradiatively to level 2. With $N_2 > N_1$, a population inversion has been created.

FIGURE 42.36 A flashlamp-pumped ruby laser.



Once a photon initiates the laser pulse, the light intensity builds quickly into a brief but incredibly intense burst of light. A typical output pulse lasts 10 ns and has an energy of 1 J. This gives a *peak power* of

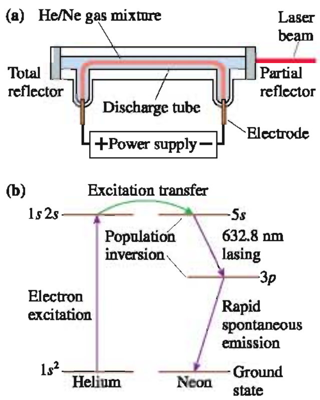
$$P = \frac{\Delta E}{\Delta t} = \frac{1\text{ J}}{10^{-8}\text{ s}} = 10^8\text{ W} = 100\text{ MW}$$

One hundred megawatts of light power! That is more than the electrical power used by a small city. The difference, of course, is that a city consumes that power continuously but the laser pulse lasts a mere 10 ns. The laser cannot fire again until the capacitor is recharged and the laser rod cooled. A typical firing rate is a few pulses per second, so the laser is "on" only a few billionths of a second out of each second.

Ruby lasers have been replaced by other pulsed lasers that, for various practical reasons, are easier to operate. However, they all operate with the same basic idea of rapid optical pumping to upper states, rapid nonradiative decay to level 2 where the population inversion is formed, then rapid build-up of an intense optical pulse.

The Helium-Neon Laser

FIGURE 42.37 A HeNe laser.



The familiar red laser used in lecture demonstrations, laboratories, and supermarket checkout scanners is the helium-neon laser, often called a HeNe laser. Its output is a *continuous,* rather than pulsed, wavelength of 632.8 nm. The medium of a HeNe laser is a mixture of $\approx$90% helium and $\approx$10% neon gases. As FIGURE 42.37a shows, the gases are sealed in a glass tube, then an electrical discharge is established along the bore of the tube. Two mirrors are bonded to the ends of the discharge tube, one a total reflector and the other having $\approx$2% transmission so that the laser beam can be extracted.

The atoms that lase are the neon atoms, but the pumping method involves the helium atoms. The electrons in the discharge collisionally excite the $1s2s$ state of helium. This state has a very small spontaneous decay rate (i.e., a very long lifetime), so it is possible to build up a fairly large population (but not an inversion) of excited helium atoms in this state. The energy of the $1s2s$ state is 20.6 eV.

Interestingly, an excited state of neon, the $5s$ state, also has an energy of 20.6 eV. If a $1s2s$ excited helium atom collides with a ground-state neon atom, as frequently happens, the excitation energy can be transferred from one atom to the other! Written as a chemical reaction, the process is

$$\text{He}^* + \text{Ne} \rightarrow \text{He} + \text{Ne}^*$$

where the asterisk indicates the atom is in an excited state. This process, called **excitation transfer,** is very efficient for the $5s$ state because the process is *resonant*—a perfect energy match. Thus the two-step process of collisional excitation of helium, followed by excitation transfer between helium and neon, pumps the neon atoms into the excited $5s$ state. This is shown in FIGURE 42.37b.

The $5s$ energy level in neon is $\approx$1.95 eV above the $3p$ state. The $3p$ state is very nearly empty of population, both because it is not efficiently populated in the discharge and because it undergoes very rapid spontaneous emission to the $3s$ states. Thus the large number of atoms pumped into the $5s$ state creates a population inversion with respect to the lower $3p$ state. These are the necessary conditions for laser action.

Because the lower level of the laser transition is normally empty of population, placing only a small fraction of the neon atoms in the $5s$ state creates a population inversion. Thus a fairly modest pumping action is sufficient to create the inversion and start the laser. Furthermore, a HeNe laser can maintain a *continuous* inversion and thus sustain continuous lasing. The electrical discharge continuously creates $5s$ excited atoms in the upper level, via excitation transfer, and the rapid spontaneous

decay of the $3p$ atoms from the lower level keeps its population low enough to sustain the inversion.

A typical helium-neon laser has a power output of 1 mW $= 10^{-3}$ J/s at 632.8 nm in a 1-mm-diameter laser beam. As you can show in a homework problem, this output corresponds to the emission of 3.2×10^{15} photons per second. Other continuous lasers operate by similar principles, but can produce much more power. The argon laser, which is widely used in scientific research, can produce up to 20 W of power at green and blue wavelengths. The carbon dioxide laser produces output power in excess of 1000 W at the infrared wavelength of 10.6 μm. It is used in industrial applications for cutting and welding.

EXAMPLE 42.9 An ultraviolet laser

An ultraviolet laser generates a 10 MW, 5.0-ns-long light pulse at a wavelength of 355 nm. How many photons are in each pulse?

SOLVE The energy of each light pulse is the power multiplied by the duration:

$$E_{\text{pulse}} = P\Delta t = (1.0 \times 10^7 \text{ W})(5.0 \times 10^{-9} \text{ s}) = 0.050 \text{ J}$$

Each photon in the pulse has energy

$$E_{\text{photon}} = hf = \frac{hc}{\lambda} = 3.50 \text{ eV} = 5.60 \times 10^{-19} \text{ J}$$

Because $E_{\text{pulse}} = NE_{\text{photon}}$, the number of photons is

$$N = \frac{E_{\text{pulse}}}{E_{\text{photon}}} = 8.9 \times 10^{16} \text{ photons}$$

SUMMARY

The goal of Chapter 42 has been to understand the structure and properties of atoms.

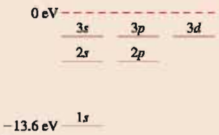
Important Concepts

Hydrogen Atom

The three-dimensional Schrödinger equation has stationary-state solutions for the hydrogen atom potential energy only if three conditions are satisfied:

- Energy $E_n = -13.60\ \text{eV}/n^2 \qquad n = 1, 2, 3, \ldots$
- Angular momentum $L = \sqrt{l(l+1)}\hbar \qquad l = 0, 1, 2, 3, \ldots, n-1$
- z-component of angular momentum
  $L_z = m\hbar \qquad m = -l, -l+1, \ldots, 0, \ldots, l-1, l$

Each state is characterized by **quantum numbers** (n, l, m), but the energy depends only on n.



The probability of finding the electron within a small distance interval δr at distance r is

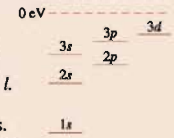
$$\text{Prob(in } \delta r \text{ at r)} = P_r(r)\delta r$$

where $P_r(r) = 4\pi r^2 |R_{nl}(r)|^2$ is the **radial probability density.**

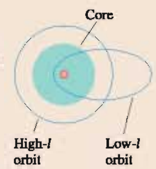
Graphs of $P_r(r)$ suggest that the electrons are arranged in shells.

Multielectron Atoms

The potential energy is electron-nucleus plus electron-electron. In the **independent particle approximation,** each electron is described by the same quantum numbers (n, l, m, m_s) used for the hydrogen atom. The energy of a state depends on n and l. For each n, energy increases as l increases.



- High-l states correspond to circular orbits. These stay outside the core.
- Low-l states correspond to elliptical orbits. These penetrate the core to interact more strongly with the nucleus. This interaction lowers their energy.



Electron spin

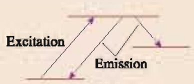
The electron has an inherent angular momentum $\vec{S}$ and magnetic moment $\vec{\mu}$ *as if* it were spinning. The spin angular momentum has a fixed magnitude $S = \sqrt{s(s+1)}\hbar$, where $s = \frac{1}{2}$. The z-component is $S_z = m_s\hbar$, where $m_s = \pm\frac{1}{2}$. These two states are called **spin-up** and **spin-down.** Each atomic state is fully characterized by the four quantum numbers (n, l, m, m_s).

The **Pauli exclusion principle** says that no more than one electron can occupy each quantum state. The periodic table of the elements is based on the fact that the ground state is the lowest-energy electron configuration compatible with the Pauli principle.

Applications

Atomic spectra are generated by excitation followed by a photon-emitting quantum jump.

- Excitation by absorption or collision
- Quantum-jump selection rule $\Delta l = \pm 1$



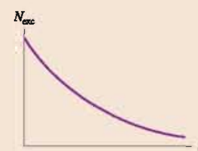
Lifetimes of excited states

The excited-state population decreases exponentially as

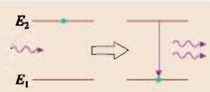
$$N_{\text{exc}} = N_0 e^{-t/\tau}$$

where $\tau = 1/r$ is the **lifetime** and r is the **decay rate.** It's not possible to predict when a particular atom will decay, but the *probability* is

$$\text{Prob(in } \delta t \text{ at } t) = r\,\delta t$$



Stimulated emission of an excited state can be caused by a photon with $E_{\text{photon}} = E_2 - E_1$. Laser action can occur if $N_2 > N_1$, a condition called a population inversion.



Terms and Notation

principal quantum number, n	spin quantum number, m_s	subshell	spontaneous emission
orbital quantum number, l	spin-up	excitation	stimulated emission
magnetic quantum number, m	spin-down	allowed transition	laser
ionization energy	independent particle approximation (IPA)	selection rule	coherent
electron cloud	Pauli exclusion principle	collisional excitation	optical cavity
radial wave function, $R_{nl}(r)$	electron configuration	nonradiative transition	population inversion
radial probability density, $P_r(r)$	closed shell	lifetime, τ	pumping
shell model		decay rate, r	excitation transfer
spin

Problem difficulty is labeled as | (straightforward) to ||| (challenging).

Problems labeled integrate significant material from earlier chapters.

CONCEPTUAL QUESTIONS

1. Consider the two hydrogen-atom states $5d$ and $4f$. Which has the higher energy? Explain.
2. What is the difference between the *probability density* and the *radial probability density?*
3. What is the difference between l and L?
4. What is the difference between s and S?
5. FIGURE Q42.5 shows the outcome of a Stern-Gerlach experiment with atoms of element X.
   a. Do the peaks represent different values of the atom's total angular momentum or different values of the z-component of its angular momentum? Explain.
   b. What quantum number characterizes the angular momentum of these atoms? Explain.

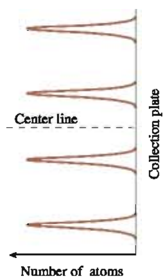

FIGURE Q42.5

6. Does each of the configurations in FIGURE Q42.6 represent a possible electron configuration of an element? If so, (i) identify the element and (ii) determine whether this is the ground state or an excited state. If not, why not?

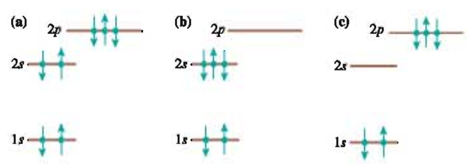

FIGURE Q42.6

7. What *is* an atom's ionization energy? In other words, if you know the ionization energy of an atom, what is it that you know about the atom?
8. Figure 42.24 shows that the ionization energy of cadmium ($Z = 48$) is larger than that of its neighbors. Why is this?
9. A neon discharge tube emits a bright reddish-orange spectrum, but a glass tube filled with neon is completely transparent. Why doesn't the neon in the tube absorb orange and red wavelengths?
10. The hydrogen atom $1s$ wave function is a maximum at $r = 0$. But the $1s$ radial probability density, shown in Figure 42.8, peaks at $r = a_B$ and is zero at $r = 0$. Explain this paradox.
11. In a multielectron atom, the lowest-l state for each n ($2s$, $3s$, $4s$, etc.) is significantly lower in energy than the hydrogen state having the same n. But the highest-l state for each n ($2p$, $3d$, $4f$, etc.) is very nearly equal in energy to the hydrogen state with the same n. Explain.
12. In FIGURE Q42.12, a photon with energy 2.0 eV is incident on an atom in the p state. Does the atom undergo an absorption transition, a stimulated emission transition, or neither? Explain.

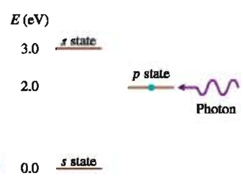

FIGURE Q42.12

EXERCISES AND PROBLEMS

Exercises

Sections 42.1–2 The Hydrogen Atom

1. | What is the angular momentum of a hydrogen atom in (a) a $4p$ state and (b) a $5f$ state? Give your answers as a multiple of $\hbar$.
2. | List the quantum numbers, excluding spin, of (a) all possible $3p$ states and (b) all possible $3d$ states.
3. | A hydrogen atom has orbital angular momentum 3.65×10^{-34} J s.
   a. What letter (s, p, d, or f) describes the electron?
   b. What is the atom's minimum possible energy? Explain.
4. | What is the maximum possible angular momentum L (as a multiple of $\hbar$) of a hydrogen atom with energy -0.544 eV?
5. | What are E and L (as a multiple of $\hbar$) of a hydrogen atom in the $6f$ state?

Section 42.3 The Electron's Spin

6. || When all quantum numbers are considered, how many different quantum states are there for a hydrogen atom with $n = 1$? With $n = 2$? With $n = 3$? List the quantum numbers of each state.
7. | How many lines of atoms would you expect to see on the collector plate of a Stern-Gerlach apparatus if the experiment is done with (a) lithium and (b) beryllium? Explain.

Section 42.4 Multielectron Atoms

Section 42.5 The Periodic Table of the Elements

8. | Predict the ground-state electron configurations of Mg, Sr, and Ba.
9. | Predict the ground-state electron configurations of P, As, and Sb.
10. | Identify the element for each of these electron configurations. Then determine whether this configuration is the ground state or an excited state.
    a. $1s^22s^22p^5$
    b. $1s^22s^22p^63s^23p^64s^23d^{10}4p$
11. | Identify the element for each of these electron configurations. Then determine whether this configuration is the ground state or an excited state.
    a. $1s^22s^22p^53d$
    b. $1s^22s^22p^63s^23p^64s^23d^6$

Section 42.6 Excited States and Spectra

12. | Show that $hc = 1240$ eV nm.
13. | What is the electron configuration of the second excited state of lithium?
14. | An electron accelerates through a 12.5 V potential difference, starting from rest, and then collides with a hydrogen atom, exciting the atom to the highest energy level allowed. List all the possible quantum-jump transitions by which the excited atom could emit a photon and the wavelength (in nm) of each.
15. | a. Is a $4p \rightarrow 4s$ transition allowed in sodium? If so, what is its wavelength (in nm)? If not, why not?
    b. Is a $3d \rightarrow 4s$ transition allowed in sodium? If so, what is its wavelength (in nm)? If not, why not?

Section 42.7 Lifetimes of Excited States

16. || An atom in an excited state has a 1.0% chance of emitting a photon in 0.10 ns. What is the lifetime of the excited state?
17. | An excited state of an atom has a 25 ns lifetime. What is the probability that an excited atom will emit a photon during a 0.50 ns interval?
18. | 1.0×10^6 sodium atoms are excited to the $3p$ state at $t = 0$ s. How many of these atoms remain in the $3p$ state at (a) $t = 10$ ns, (b) $t = 30$ ns, and (c) $t = 100$ ns?
19. || 1.0×10^6 atoms are excited to an upper energy level at $t = 0$ s. At the end of 20 ns, 90% of these atoms have undergone a quantum jump to the ground state.
    a. How many photons have been emitted?
    b. What is the lifetime of the excited state?
20. || 1.0×10^8 sodium atoms and 1.0×10^8 potassium atoms are simultaneously excited to the $3p$ state and $4p$ state, respectively. How many potassium atoms remain in the $4p$ state when 80% of the excited sodium atoms have decayed?

Section 42.8 Stimulated Emission and Lasers

21. | A 1.0 mW helium neon laser emits a visible laser beam with a wavelength of 633 nm. How many photons are emitted per second?
22. | A carbon dioxide laser emits 5.0×10^{22} photons/s at an infrared wavelength of 10.6 μm. What is the laser's power output?
23. | A laser emits 1.0×10^{19} photons per second from an excited state with energy $E_2 = 1.17$ eV. The lower energy level is $E_1 = 0$ eV.
    a. What is the wavelength of this laser?
    b. What is the power output of this laser?

Problems

24. || a. Draw a diagram similar to Figure 42.3 to show all the possible orientations of the angular momentum vector $\vec{L}$ for the case $l = 3$. Label each $\vec{L}$ with the appropriate value of m.
    b. What is the minimum angle between $\vec{L}$ and the z-axis?
25. || There exist subatomic particles whose spin is characterized by $s = 1$, rather than the $s = \frac{1}{2}$ of electrons. These particles are said to have a spin of one.
    a. What is the magnitude (as a multiple of $\hbar$) of the spin angular momentum S for a particle with a spin of one?
    b. What are the possible values of the spin quantum number?
    c. Draw a vector diagram similar to Figure 42.14 to show the possible orientations of $\vec{S}$.
26. || A hydrogen atom has $l = 2$. What are the (a) minimum (as a multiple of $\hbar$) and (b) maximum values of the quantity $(L_x^2 + L_y^2)^{1/2}$?
27. | A hydrogen atom in its fourth excited state emits a photon with a wavelength of 1282 nm. What is the atom's maximum possible orbital angular momentum (as a multiple of $\hbar$) after the emission?
28. | Calculate (a) the radial wave function and (b) the radial probability density at $r = \frac{1}{2}a_B$ for an electron in the $1s$ state of hydrogen. Give your answers in terms of a_B.
29. || For an electron in the $1s$ state of hydrogen, what is the probability of being in a spherical shell of thickness $0.010a_B$ at distance (a) $\frac{1}{2}a_B$, (b) a_B, and (c) $2a_B$ from the proton?

30. || Prove that the normalization constant of the $1s$ radial wave function of the hydrogen atom is $(\pi a_B^3)^{-1/2}$, as given in Equation 42.7.
Hint: A useful definite integral is

$$\int_0^\infty x^n e^{-ax}\,dx = \frac{n!}{a^{n+1}}$$

31. || Prove that the normalization constant of the $2p$ radial wave function of the hydrogen atom is $(24\pi a_B^3)^{-1/2}$, as shown in Equation 42.7.
Hint: See the hint in Problem 30.

32. || Prove that the radial probability density peaks at $r = a_B$ for the $1s$ state of hydrogen.

33. || a. Calculate and graph the hydrogen radial wave function $R_{2p}(r)$ over the interval $0 \le r \le 8a_B$.
b. Determine the value of r (in terms of a_B) for which $R_{2p}(r)$ is a maximum.
c. Example 42.3 and Figure 42.8 showed that the radial probability density for the $2p$ state is a maximum at $r = 4a_B$. Explain why this differs from your answer to part b.

34. || In general, an atom can have both orbital angular momentum and spin angular momentum. The *total* angular momentum is defined to be $\vec{J} = \vec{L} + \vec{S}$. The total angular momentum is quantized in the same way as $\vec{L}$ and $\vec{S}$. That is, $J = \sqrt{j(j+1)}\hbar$, where j is the total angular momentum quantum number. The z-component of $\vec{J}$ is $J_z = L_z + S_z = m_j\hbar$, where m_j goes in integer steps from $-j$ to $+j$. Consider a hydrogen atom in a p state, with $l = 1$.
a. L_z has three possible values and S_z has two. List all possible combinations of L_z and S_z. For each, compute J_z and determine the quantum number m_j. Put your results in a table.
b. The number of values of J_z that you found in part a is too many to go with a single value of j. But you should be able to divide the values of J_z into two groups that correspond to two values of j. What are the allowed values of j? Explain. In a classical atom, there would be no restrictions on how the two angular momenta $\vec{L}$ and $\vec{S}$ can combine. Quantum mechanics is different. You've now shown that there are only two allowed ways to add these two angular momenta.

35. | Draw a series of pictures, similar to Figure 42.22, for the ground states of K, Ti, Fe, Ge, and Br.

36. | Draw a series of pictures, similar to Figure 42.22, for the ground states of Ca, V, Ni, As, and Kr.

37. || a. What downward transitions are possible for a sodium atom in the $6s$ state? (See Figure 42.25.)
b. What are the wavelengths of the photons emitted in each of these transitions?

38. | The $5d \rightarrow 3p$ transition in the emission spectrum of sodium has a wavelength of 499 nm. What is the energy of the $5d$ state?

39. | A sodium atom emits a photon with wavelength 818 nm shortly after being struck by an electron. What minimum speed did the electron have before the collision?

40. || The ionization energy of an atom is known to be 5.5 eV. The emission spectrum of this atom contains only the four wavelengths 310.0 nm, 354.3 nm, 826.7 nm, and 1240.0 nm. Draw an energy-level diagram with the fewest possible energy levels that agrees with these experimental data. Label each level with an appropriate l quantum number.
Hint: Don't forget about the Δl selection rule.

41. || FIGURE P42.41 shows the first few energy levels of the lithium atom. Make a table showing all the allowed transitions in the emission spectrum. For each transition, indicate
a. The wavelength, in nm.
b. Whether the transition is in the infrared, the visible, or the ultraviolet spectral region.
c. Whether or not the transition would be observed in the lithium absorption spectrum.

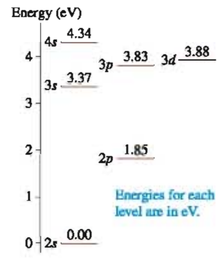

FIGURE P42.41

42. || FIGURE P42.42 shows a few energy levels of the mercury atom.
a. Make a table showing all the allowed transitions in the emission spectrum. For each transition, indicate the photon wavelength, in nm.
b. What minimum speed must an electron have to excite the 492-nm-wavelength blue emission line in the Hg spectrum?

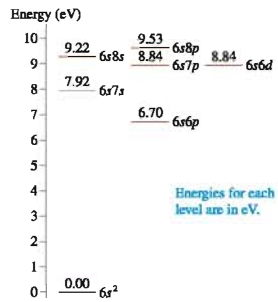

FIGURE P42.42

43. || Suppose you put five electrons into a 0.50-nm-wide one-dimensional rigid box (i.e., an infinite potential well).
a. Use an energy-level diagram to show the electron configuration of the ground state.
b. What is the ground-state energy?

44. || Three electrons are in a one-dimensional rigid box (i.e., an infinite potential well) of length 0.5 nm. Two are in the $n = 1$ state and one is in the $n = 6$ state. The selection rule for the rigid box allows only those transitions for which Δn is odd.
a. Draw an energy-level diagram. On it, show the filled levels and show all transitions that could emit a photon.
b. What are all the possible wavelengths that could be emitted by this system?

45. || a. What is the decay rate for the $2p$ state of hydrogen?
b. During what interval of time will 10% of a sample of $2p$ hydrogen atoms decay?

46. || A hydrogen atom is in the $2p$ state. How much time must elapse for there to be a 1% chance that this atom will undergo a quantum jump to the ground state?

47. ||| An atom in an excited state has a 1.0% chance of emitting a photon in 0.20 ns. How long will it take for 25% of a sample of excited atoms to decay?

48. ‖ a. Find an expression in terms of τ for the *half-life* $t_{1/2}$ of a sample of excited atoms. The half-life is the time at which half of the excited atoms have undergone a quantum jump and emitted a photon.
   b. What is the half-life of the $3p$ state of sodium?
49. ‖ An electrical discharge in a neon-filled tube maintains a *steady* population of 1.0×10^9 atoms in an excited state with $\tau = 20$ ns. How many photons are emitted per second from atoms in this state?
50. ‖ A ruby laser emits a 100 MW, 10-ns-long pulse of light with a wavelength of 690 nm. How many chromium atoms undergo stimulated emission to generate this pulse?

Challenge Problems

51. Two excited energy levels are separated by the very small energy difference ΔE. As atoms in these levels undergo quantum jumps to the ground state, the photons they emit have nearly identical wavelengths λ.
   a. Show that the wavelengths differ by
   $$\Delta\lambda = \frac{\lambda^2}{hc}\Delta E$$
   b. In the Lyman series of hydrogen, what is the wavelength difference between photons emitted in the $n = 20$ to $n = 1$ transition and photons emitted in the $n = 21$ to $n = 1$ transition?
52. What is the probability of finding a $1s$ hydrogen electron at distance $r > a_B$ from the proton?
53. What is the probability of finding a $1s$ hydrogen electron at distance $r < \frac{1}{2}a_B$ from the proton?
54. Prove that the most probable distance from the proton of an electron in the $2s$ state of hydrogen is $5.236a_B$.
55. Find the distance, in terms of a_B, between the two peaks in the radial probability density of the $2s$ state of hydrogen.
   Hint: This problem requires a numerical solution.
56. Suppose you have a machine that gives you pieces of candy when you push a button. Eighty percent of the time, pushing the button gets you two pieces of candy. Twenty percent of the time, pushing the button yields 10 pieces. The *average* number of pieces per push is $N_{avg} = 2 \times 0.80 + 10 \times 0.20 = 3.6$. That is, 10 pushes should get you, on average, 36 pieces. Mathematically, the average value when the probabilities differ is $N_{avg} = \sum(N_i \times \text{Probability of } i)$. We can do the same thing in quantum mechanics, with the difference that the sum becomes an integral. If you measured the distance of the electron from the proton in many hydrogen atoms, you would get many values, as indicated by the radial probability density. But the *average* value of r would be
   $$r_{avg} = \int_0^\infty rP_r(r)\,dr$$
   Calculate the average value of r in terms of a_B for the electron in the $1s$ and the $2p$ states of hydrogen.
57. The 1997 Nobel prize in physics went to Steven Chu, Claude Cohen-Tannoudji, and William Phillips for their development of techniques to slow, stop, and "trap" atoms with laser light. To see how this works, consider a beam of rubidium atoms (mass 1.4×10^{-25} kg) traveling at 500 m/s after being evaporated out of an oven. A laser beam with a wavelength of 780 nm is directed against the atoms. This is the wavelength of the $5s \rightarrow 5p$ transition in rubidium, with $5s$ being the ground state, so the photons in the laser beam are easily absorbed by the atoms. After an average time of 15 ns, an excited atom spontaneously emits a 780-nm-wavelength photon and returns to the ground state.
   a. The energy-momentum-mass relationship of Einstein's theory of relativity is $E^2 = p^2c^2 + m^2c^4$. A photon is massless, so the momentum of a photon is $p = E_{photon}/c$. Assume that the atoms are traveling in the positive x-direction and the laser beam in the negative x-direction. What is the initial momentum of an atom leaving the oven? What is the momentum of a photon of light?
   b. The total momentum of the atom and the photon must be conserved in the absorption processes. As a consequence, how many photons must be absorbed to bring the atom to a halt?

   NOTE ▶ Momentum is also conserved in the emission processes. However, spontaneously emitted photons are emitted in random directions. Averaged over many absorption/emission cycles, the net recoil of the atom due to emission is zero and can be ignored. ◀

   c. Assume that the laser beam is so intense that a ground-state atom absorbs a photon instantly. How much time is required to stop the atoms?
   d. Use Newton's second law in the form $F = \Delta p/\Delta t$ to calculate the force exerted on the atoms by the photons. From this, calculate the atoms' acceleration as they slow.
   e. Over what distance is the beam of atoms brought to a halt?

STOP TO THINK ANSWERS

Stop to Think 42.1: $n = 3, l = 1$, or a $3p$ state.

Stop to Think 42.2: 4. You can see in Figure 42.8 that the ns state has n maxima.

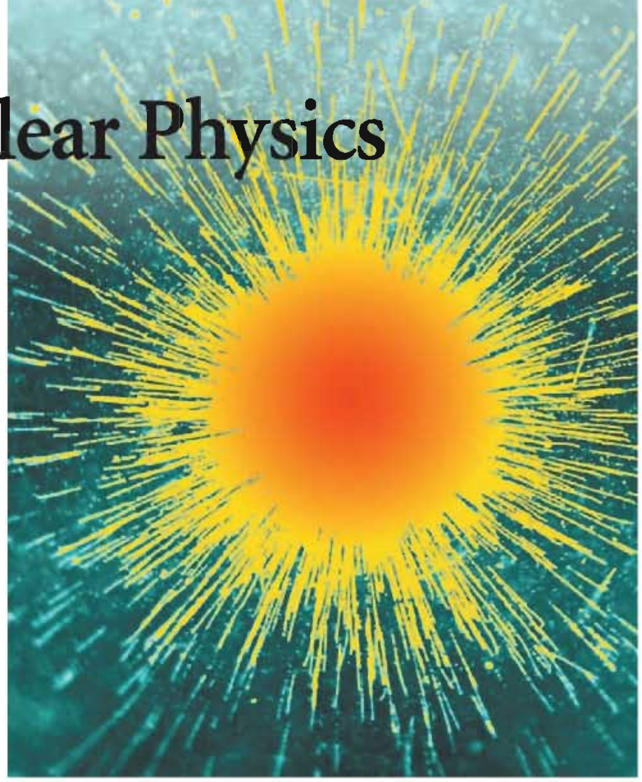
Stop to Think 42.3: No. $m_s = \pm\frac{1}{2}$, so the z-component S_z cannot be zero.

Stop to Think 42.4: b. The atom would have less energy if the $3s$ electron were in a $2p$ state.

Stop to Think 42.5: c. Emission is a quantum jump to a lower-energy state. The $5p \rightarrow 4p$ transition is not allowed because $\Delta l = 0$ violates the selection rule. The lowest-energy allowed transition is $5p \rightarrow 3d$, with $E_{photon} = \Delta E_{atom} = 3.0$ eV.

Stop to Think 42.6: e. Because $r_B = 2r_A$, the ratio is $e^{-2}/e^{-1} = e^{-1} < \frac{1}{2}$.

43 Nuclear Physics



A photographic emulsion records the tracks of alpha particles emitted by a speck of radium.

▶ Looking Ahead
The goal of Chapter 43 is to understand the physics of the nucleus and some of the applications of nuclear physics. In this chapter you will learn to:

- Interpret the basic structure of the nucleus.
- Understand how the strong force holds the nucleus together.
- Understand why some nuclei are unstable and undergo radioactive decay.
- Calculate the half-lives of radioactive decay.
- Apply nuclear physics to biology and medicine.

◀ Looking Back
The material in this chapter depends on basic atomic structure and on the quantized energy levels in potential-energy wells. Please review:

- Sections 38.6 and 38.7 Rutherford's model of the nucleus.
- Section 41.6 Finite potential-energy wells.

The nucleus of the atom is extremely remote from our everyday experience. Thus it comes as something of a surprise to notice the extent to which nuclear physics has become part of our modern technology and contemporary vocabulary: nuclear power and nuclear weapons, nuclear medicine and nuclear waste, nuclear fission and nuclear fusion.

Rutherford's discovery of the atomic nucleus marked the beginning of nuclear physics. Other physicists were soon designing experiments to probe within the nucleus and learn the properties of nuclear matter. In this final chapter, we'll explore the physics of the nucleus and look at some applications of nuclear physics.

43.1 Nuclear Structure

The 1890s was a decade of mysterious rays. Cathode rays were being studied in several laboratories, and, in 1895, Röntgen discovered x rays. In 1896, after hearing of Röntgen's discovery, the French scientist A. H. Becquerel wondered if mineral crystals that fluoresce after exposure to sunlight were emitting x rays. He put a piece of film in an opaque envelope, then placed a crystal on top and left it in the sun. To his delight, the film in the envelope was exposed.

Becquerel thought he had discovered x rays coming from crystals, but his joy was short lived. He soon found that the film could be exposed equally well simply by being stored in a closed drawer with the crystals. Further investigation showed that the crystal, which happened to be a mineral containing uranium, was spontaneously

emitting some new kind of ray. Rather than finding x rays, as he had hoped, Becquerel had discovered what became known as *radioactivity.*

Ernest Rutherford soon took up the investigation and found not one but three distinct kinds of rays emitted from crystals containing uranium. Not knowing what they were, he named them for their ability to penetrate matter and ionize air. The first, which caused the most ionization and penetrated the least, he called *alpha rays*. The second, with intermediate penetration and ionization, were *beta rays,* and the third, with the least ionization but the largest penetration, became *gamma rays.*

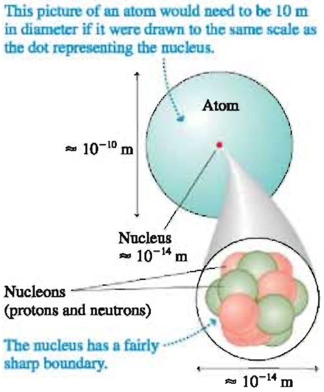
Within a few years, Rutherford was able to show that alpha rays are helium nuclei emitted from the crystal at very high velocities. These became the projectiles that he used in 1909 to probe the structure of the atom. The outcome of that experiment, as you learned in Chapter 38, was Rutherford's discovery that atoms have a very small, dense nucleus at the center.

Rutherford's discovery of the nucleus may have settled the question of atomic structure, but it raised many new issues for scientific research. Foremost among them were:

- What is nuclear matter? What are its properties?
- What holds the nucleus together? Why doesn't the repulsive electrostatic force blow it apart?
- What is the connection between the nucleus and radioactivity?

These questions were the beginnings of **nuclear physics,** the study of the properties of the atomic nucleus.

FIGURE 43.1 The nucleus is a tiny speck within an atom.



Nucleons

The nucleus is a tiny speck in the center of a vastly larger atom. As FIGURE 43.1 shows, the nuclear diameter of roughly 10^{-14} m is only about 1/10,000 the diameter of the atom. What we call *matter* is overwhelmingly empty space!

You learned in Chapter 38 that the nucleus is composed of two types of particles: *protons* and *neutrons*. Together, these are referred to as **nucleons.** The role of the neutrons, which have nothing to do with keeping electrons in orbit, is an important issue that we'll address in this chapter. Table 43.1 summarizes the basic properties of protons and neutrons.

As you can see, protons and neutrons are virtually identical other than that the proton has one unit of the fundamental charge e whereas the neutron is electrically neutral. The neutron is slightly more massive than the proton, but the difference is very small, only about 0.1%. Notice that the proton and neutron, like the electron, have an *inherent angular momentum* and magnetic moment with spin quantum number $s = \frac{1}{2}$. As a consequence, protons and neutrons obey the Pauli exclusion principle.

The number of protons Z is the element's **atomic number.** In fact, an element is identified by the number of protons in the nucleus, not by the number of orbiting electrons. Electrons are easily added and removed, forming negative and positive ions, but doing so doesn't change the element. The **mass number** A is defined to be $A = Z + N$, where N is the **neutron number.** The mass number is the total number of nucleons in a nucleus.

TABLE 43.1 Protons and neutrons

	Proton	Neutron
Number	Z	N
Charge q	$+e$	0
Spin s	$\frac{1}{2}$	$\frac{1}{2}$
Mass, in u	1.00728	1.00866

NOTE ▶ The mass number, which is dimensionless, is *not* the same thing as the atomic mass m. We'll look at actual atomic masses later. ◀

Isotopes and Isobars

It was discovered early in the 20th century that not all atoms of the same element (same Z) have the same mass. There are a *range* of neutron numbers that happily form a nucleus with Z protons, creating a group of nuclei having the same Z-value (i.e., they are all the same chemical element) but different A-values. The atoms of an element with different values of A are called **isotopes** of that element.

Chemical behavior is determined by the orbiting electrons. All isotopes of one element have the same number of orbiting electrons (if the atoms are electrically neutral) and thus have the same chemical properties, but different isotopes of the same element can have quite different nuclear properties.

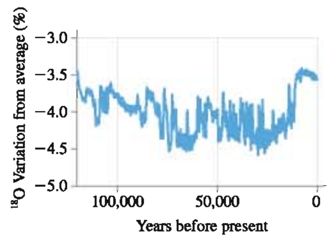
The notation used to label isotopes is ^{A}Z, where the mass number A is given as a *leading* superscript. The proton number Z is not specified by an actual number but, equivalently, by the chemical symbol for that element. Hence ordinary carbon, which has six protons and six neutrons in the nucleus, is written ^{12}C and pronounced "carbon twelve." The radioactive form of carbon used in carbon dating is ^{14}C. It has six protons, making it carbon, and eight neutrons.

More than 3000 isotopes are known. The majority of these are **radioactive,** meaning that the nucleus is not stable but, after some period of time, will either fragment or emit some kind of subatomic particle in an effort to reach a more stable state. Many of these radioactive isotopes are created by nuclear reactions in the laboratory and have only a fleeting existence. Only 266 isotopes are **stable** (i.e., nonradioactive) and occur in nature. We'll begin to look at the issue of nuclear stability in the next section.

The *naturally occurring* nuclei include the 266 stable isotopes and a handful of radioactive isotopes with such long half-lives, measured in billions of years, that they also occur naturally. The most well-known example of a naturally occurring radioactive isotope is the uranium isotope ^{238}U. For each element, the fraction of naturally occurring nuclei represented by one particular isotope is called the **natural abundance** of that isotope.

Although there are many radioactive isotopes of the element iodine, iodine occurs *naturally* only as ^{127}I. Consequently, we say that the natural abundance of ^{127}I is 100%. Most elements have multiple naturally occurring isotopes. The natural abundance of ^{14}N is 99.6%, meaning that 996 out of every 1000 naturally occurring nitrogen atoms are the isotope ^{14}N. The remaining 0.4% of naturally occurring nitrogen is the isotope ^{15}N, with one extra neutron.

A series of nuclei having the same A-value (the same mass number) but different values of Z and N are called **isobars.** For example, the three nuclei ^{14}C, ^{14}N, and ^{14}O are isobars with $A = 14$. Only ^{14}N is stable; the other two are radioactive.



When water freezes to make snow crystals, the fraction of molecules containing ^{18}O is greater for snow that forms at higher atmospheric temperatures. Snow accumulating over tens of thousands of years has built up a thick ice sheet in Greenland. A core sample of this ice gives a record of the isotopic composition of the snow that fell over this time period. Higher numbers on the graph correspond to higher average temperatures. Broad trends, such as the increase in temperature at the end of the last ice age, are clearly seen.

Atomic Mass

You learned in Chapter 16 that atomic masses are specified in terms of the *atomic mass unit* u, defined such that the atomic mass of the isotope ^{12}C is exactly 12 u. The conversion to SI units is

$$1\text{ u} = 1.6605 \times 10^{-27}\text{ kg}$$

Alternatively, we can use Einstein's $E_0 = mc^2$ to express masses in terms of their energy equivalent. The energy equivalent of 1 u of mass is

$$\begin{aligned} E_0 &= (1.6605 \times 10^{-27}\text{ kg})(2.9979 \times 10^8\text{ m/s})^2 \\ &= 1.4924 \times 10^{-10}\text{ J} = 931.49\text{ MeV} \end{aligned} \tag{43.1}$$

Thus the atomic mass unit can be written

$$1\text{ u} = 931.49\text{ MeV}/c^2$$

It may seem unusual, but the units MeV/c^2 are units of mass.

NOTE ▶ We're using more significant figures than usual. Many nuclear calculations look for the small difference between two masses that are almost the same. Those two masses must be calculated or specified to four or five significant figures if their difference is to be meaningful. ◀

TABLE 43.2 Some atomic masses

Particle	Symbol	Mass (u)	Mass (MeV/c^2)
Electron	e	0.00055	0.51
Proton	p	1.00728	938.28
Neutron	n	1.00866	939.57
Hydrogen	^{1}H	1.00783	938.79
Deuterium	^{2}H	2.01410	1876.12
Helium	^{4}He	4.00260	3728.40

Table 43.2 shows the atomic masses of the electron, the nucleons, and three important light elements. Appendix C contains a more complete list. Notice that the mass of a hydrogen atom is the sum of the masses of a proton and an electron. But a quick calculation shows that the mass of a helium atom (2 protons, 2 neutrons, and 2 electrons) is 0.03038 u less than the sum of the masses of its constituents. The difference is due to the binding energy of the nucleus, a topic we'll look at in Section 43.2.

The isotope ^{2}H is a hydrogen atom in which the nucleus is not simply a proton but a proton and a neutron. Although the isotope is a form of hydrogen, it is called **deuterium.** The natural abundance of deuterium is 0.015%, or about 1 out of every 6700 hydrogen atoms. Water made with deuterium (sometimes written D_2O rather than H_2O) is called *heavy water.*

NOTE ▶ Don't let the name *deuterium* cause you to think this is a different element. Deuterium is an isotope of hydrogen. Chemically, it behaves just like ordinary hydrogen. ◀

The *chemical* atomic mass shown on the periodic table of the elements is the *weighted average* of the atomic masses of all naturally occurring isotopes. For example, chlorine has two stable isotopes: ^{35}Cl, with $m = 34.97$ u, is 75.8% abundant and ^{37}Cl, at 36.97 u, is 24.2% abundant. The average, weighted by abundance, is $0.758 \times 34.97 + 0.242 \times 36.97 = 35.45$. This is the value shown on the periodic table and is the correct value for most chemical calculations, but it is not the mass of any particular isotope of chlorine.

NOTE ▶ The atomic masses of the proton and the neutron are both ≈ 1 u. Consequently, the value of the mass number A is *approximately* the atomic mass in u. The approximation $m \approx A$ u is sufficient in many contexts, such as when we're calculating the masses of atoms in the kinetic theory of gases, but in nuclear physics calculations, we almost always need the more accurate mass values that you find in Table 43.2 or Appendix C. ◀

Nuclear Size and Density

Unlike the atom's electron cloud, which is quite diffuse, the nucleus has a fairly sharp boundary. Experimentally, the radius of a nucleus with mass number A is found to be

$$r = r_0 A^{1/3} \tag{43.2}$$

where $r_0 = 1.2$ fm. Recall that 1 fm $=$ 1 femtometer $= 10^{-15}$ m.

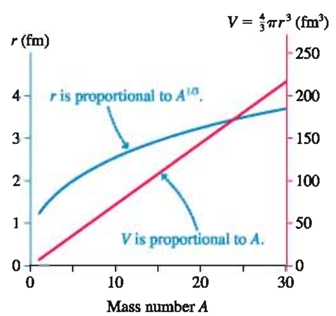


FIGURE 43.2 The nuclear radius and volume as a function of A.

As FIGURE 43.2 shows, the radius is proportional to $A^{1/3}$. Consequently, the volume of the nucleus (proportional to r^3) is directly proportional to A, the number of nucleons. A nucleus with twice as many nucleons will occupy twice as much volume. This finding has three implications:

- Nucleons are incompressible. Adding more nucleons doesn't squeeze the inner nucleons into a smaller volume.
- The nucleons are tightly packed, looking much like the drawing in Figure 43.1.
- Nuclear matter has a constant density.

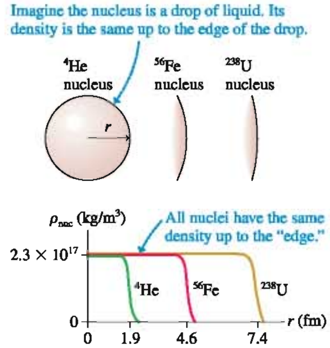
In fact, we can use Equation 43.2 to estimate the density of nuclear matter. Consider a nucleus with mass number A. Its mass, within 1%, is A atomic mass units. Thus

$$\rho_{\text{nuc}} \approx \frac{A\text{ u}}{\frac{4}{3}\pi r^3} = \frac{A\text{ u}}{\frac{4}{3}\pi r_0^3 A} = \frac{1\text{ u}}{\frac{4}{3}\pi r_0^3} = \frac{1.66 \times 10^{-27}\text{ kg}}{\frac{4}{3}\pi(1.2 \times 10^{-15}\text{ m})^3} \tag{43.3}$$
$$= 2.3 \times 10^{17}\text{ kg/m}^3$$

The fact that A cancels means that **all nuclei have this density.** It is a staggeringly large density, roughly 10^{14} times larger than the density of familiar liquids and solids. One early objection to Rutherford's model of a nuclear atom was that matter simply couldn't have a density this high. Although we have no direct experience with such matter, nuclear matter really is this dense.

FIGURE 43.3 shows the density profiles of three nuclei. The constant density right to the edge is analogous to that of a drop of incompressible liquid, and, indeed, one successful model of many nuclear properties is called the **liquid-drop model.** Notice that the range of nuclear radii, from small helium to large uranium, is not quite a factor of 4. The fact that ^{56}Fe is a fairly typical atom in the middle of the periodic table is the basis for our earlier assertion that the nuclear diameter is roughly 10^{-14} m, or 10 fm.

FIGURE 43.3 Density profiles of three nuclei.

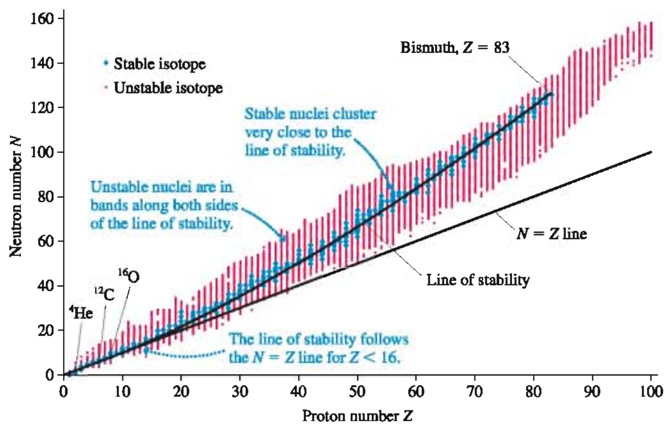


STOP TO THINK 43.1 Three electrons orbit a neutral ^{6}Li atom. How many electrons orbit a neutral ^{7}Li atom?

43.2 Nuclear Stability

We've noted that fewer than 10% of the known nuclei are stable (i.e., not radioactive). Because nuclei are characterized by two independent numbers, N and Z, it is useful to show the known nuclei on a plot of neutron number N versus proton number Z. **FIGURE 43.4** shows such a plot. Stable nuclei are represented by blue diamonds and unstable, radioactive nuclei by red dots.

FIGURE 43.4 Stable and unstable nuclei shown on a plot of neutron number N versus proton number Z.



We can make several observations from this graph:

- The stable nuclei cluster very close to the curve called the **line of stability.**
- There are no stable nuclei with $Z > 83$ (bismuth).
- Unstable nuclei are in bands along both sides of the line of stability.
- The lightest elements, with $Z < 16$, are stable when $N \approx Z$. The familiar elements ^{4}He, ^{12}C, and ^{16}O all have equal numbers of protons and neutrons.
- As Z increases, the number of neutrons needed for stability grows increasingly larger than the number of protons. The N/Z ratio is ≈ 1.2 at $Z = 40$ but has grown to ≈ 1.5 at $Z = 80$.

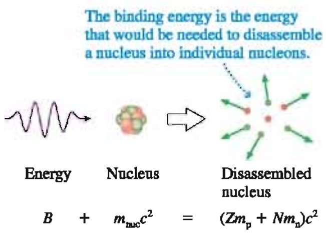
These observations—especially $N \approx Z$ for small Z but $N > Z$ for large Z—cry out for an explanation. The quantum-mechanical model of the nucleus that we'll develop in Section 43.4 will provide the explanation we seek.

STOP TO THINK 43.2 The isobars corresponding to one specific value of A are found on the plot of Figure 43.4 along

a. A vertical line.
b. A horizontal line.
c. A diagonal line that goes up and to the left.
d. A diagonal line that goes up and to the right.

Binding Energy

FIGURE 43.5 The nuclear binding energy.



19.2 ActivPhysics ONLINE

A nucleus is a *bound system.* That is, you would need to supply energy to disperse the nucleons by breaking the nuclear bonds between them. FIGURE 43.5 shows this idea schematically.

You learned a similar idea in atomic physics. The energy levels of the hydrogen atom are negative numbers because the bound system has less energy than a free proton and electron. The energy you must supply to an atom to remove an electron is called the *ionization energy.*

In much the same way, the energy you would need to supply to a nucleus to disassemble it into individual protons and neutrons is called the **binding energy.** Whereas ionization energies of atoms are only a few eV, the binding energies of nuclei are tens or hundreds of MeV, energies large enough that their mass equivalent is not negligible.

Consider a nucleus with mass m_{nuc}. It is found experimentally that m_{nuc} is *less* than the total mass $Zm_p + Nm_n$ of the Z protons and N neutrons that form the nucleus, where m_p and m_n are the masses of the proton and neutron. That is, the energy equivalent $m_{nuc}c^2$ of the nucleus is less than the energy equivalent $(Zm_p + Nm_n)c^2$ of the individual nucleons. The binding energy B of the nucleus (not the entire atom) is defined as

$$B = (Zm_p + Nm_n - m_{nuc})c^2 \qquad (43.4)$$

This is the energy you would need to supply to disassemble the nucleus into its pieces.

The practical difficulty is that laboratory scientists use mass spectroscopy to measure *atomic* masses, not nuclear masses. The atomic mass m_{atom} is m_{nuc} plus the mass Zm_e of Z orbiting electrons. (Strictly speaking, we should allow for the binding energy of the electrons, but these binding energies are roughly a factor of 10^6 smaller than the nuclear binding energies and can be neglected in all but the most precise measurements and calculations.)

Fortunately, we can switch from the nuclear mass to the atomic mass by the simple trick of both adding and subtracting Z electron masses. We begin by writing Equation 43.4 in the equivalent form

$$B = (Zm_p + Zm_e + Nm_n - m_{nuc} - Zm_e)c^2 \qquad (43.5)$$

Now $m_{nuc} + Zm_e = m_{atom}$, the atomic mass, and $Zm_p + Zm_e = Z(m_p + m_e) = Zm_H$, where m_H is the mass of a hydrogen *atom.* Finally, we use the conversion factor $1\text{ u} = 931.49\text{ MeV}/c^2$ to write $c^2 = 931.49\text{ MeV/u}$. The binding energy is then

$$B = (Zm_H + Nm_n - m_{atom}) \times (931.49\text{ MeV/u}) \qquad (43.6)$$
(binding energy)

where all three masses are in atomic mass units.

EXAMPLE 43.1 The binding energy of iron

What is the binding energy of the ^{56}Fe nucleus?

SOLVE The isotope ^{56}Fe has $Z = 26$ and $N = 30$. The atomic mass of ^{56}Fe, found in Appendix C, is 55.9349 u. Thus the mass difference between the ^{56}Fe nucleus and its constituents is

$$B = 26(1.0078\text{ u}) + 30(1.0087\text{ u}) - 55.9349\text{ u} = 0.529\text{ u}$$

where, from Table 43.2, 1.0078 u is the mass of the hydrogen atom. Thus the binding energy of ^{56}Fe is

$$B = (0.529\text{ u}) \times (931.49\text{ MeV/u}) = 493\text{ MeV}$$

ASSESS The binding energy is extremely large, the energy equivalent of more than half the mass of a proton or a neutron.

The nuclear binding energy increases as A increases simply because there are more nuclear bonds. A more useful measure for comparing one nucleus to another is the quantity B/A, called the *binding energy per nucleon.* Iron, with $B = 493$ MeV and $A = 56$, has 8.80 MeV per nucleon. This is the amount of energy, on average, you would need to supply in order to remove *one* nucleon from the nucleus. Nuclei with larger values of B/A are more tightly held together than nuclei with smaller values of B/A.

FIGURE 43.6 The curve of binding energy.

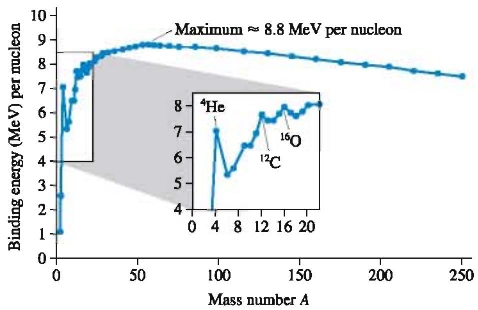


FIGURE 43.6 is a graph of the binding energy per nucleon versus mass number A. The line connecting the points is often called the **curve of binding energy.** This curve has three important features:

- There are peaks in the binding energy curve at $A = 4$, 12, and 16. The one at $A = 4$, corresponding to ^4He, is especially pronounced. As you'll see, these peaks, which represent nuclei more tightly bound than their neighbors, are due to *closed shells* in much the same way that the graph of atomic ionization energies (see Figure 42.24) peaked for closed electron shells.
- The binding energy per nucleon is *roughly* constant at ≈8 MeV per nucleon for $A > 20$. This suggests that, as a nucleus grows, there comes a point where the nuclear bonds are *saturated.* Each nucleon interacts only with its nearest neighbors, the ones it's actually touching. This, in turn, implies that the nuclear force is a *short-range* force.
- The curve has a broad maximum at $A \approx 60$. This will be important for our understanding of radioactivity. In principle, heavier nuclei could become *more* stable (more binding energy per nucleon) by breaking into smaller pieces. Lighter nuclei could become *more* stable by fusing together into larger nuclei. There may not always be a mechanism for such nuclear transformations to take place, but *if* there is a mechanism, it is energetically favorable for it to occur.

43.3 The Strong Force

Rutherford's discovery of the atomic nucleus was not immediately accepted by all scientists. Their primary objection was that the protons would blow themselves apart at tremendously high speeds due to the extremely large electrostatic forces between them at a separation of a few femtometers. No known force could hold the nucleus together.

It soon became clear that a previously unknown force of nature operates within the nucleus to hold the nucleons together. This new force had to be stronger than the repulsive electrostatic force; hence it was named the **strong force.** It is also called the *nuclear force.*

The strong force has four important properties:

1. It is an *attractive* force between any two nucleons.
2. It does not act on electrons.
3. It is a *short-range* force, acting only over nuclear distances.
4. Over the range where it acts, it is *stronger* than the electrostatic force that tries to push two protons apart.

The fact that the strong force is short-range, in contrast to the long-range $1/r^2$ electric, magnetic, and gravitational forces, is apparent from the fact that we see no evidence for nuclear forces outside the nucleus.

FIGURE 43.7 The strong force is the same between any two nucleons.

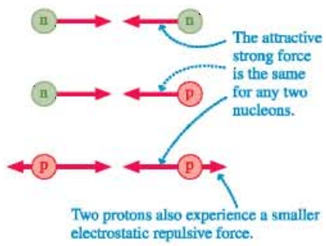

FIGURE 43.7 summarizes the three interactions that take place within the nucleus. Whether the strong force between two protons is the same strength as the force between two neutrons or between a proton and a neutron is an important question that can be answered experimentally. The primary means of investigating the strong force is to accelerate a proton to very high speed, using a cyclotron or some other particle accelerator, then to study how the proton is scattered by various target materials.

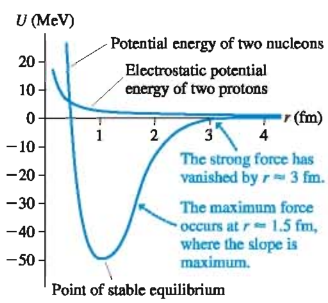
The conclusion of many decades of research is that the strong force between two nucleons is independent of whether they are protons or neutrons. Charge is the basis for electromagnetic interactions, but it is of no relevance to the strong force. Protons and neutrons are identical as far as nuclear forces are concerned.

Potential Energy

FIGURE 43.8 The potential-energy diagram for two nucleons interacting via the strong force.



Unfortunately, there's no simple formula to calculate the strong force or the potential energy of two nucleons interacting via the strong force. FIGURE 43.8 is an experimentally determined potential-energy diagram for two interacting nucleons, with r the distance between their centers. The potential-energy minimum at $r \approx 1$ fm is a point of stable equilibrium.

Recall that the force is the negative of the slope of a potential-energy diagram. The steeply rising potential for $r < 1$ fm represents a strongly repulsive force. That is, the nucleon "cores" strongly repel each other if they get too close together. The force is attractive for $r > 1$ fm, where the slope is positive, and it is strongest where the slope is steepest, at $r \approx 1.5$ fm. The strength of the force quickly decreases for $r > 1.5$ fm and is zero for $r > 3$ fm. That is, the strong force represented by this potential energy is effective only over a very short range of distances.

Notice how small the electrostatic energy of two protons is in comparison to the potential energy of the strong force. At $r \approx 1.0$ fm, the point of stable equilibrium, the magnitude of the nuclear potential energy is ≈ 100 times larger than the electrostatic potential energy.

A question asked earlier was why the nucleus has neutrons at all. The answer is related to the short range of the strong force. Protons throughout the nucleus exert repulsive electrostatic forces on each other, but, because of the short range of the strong force, a proton feels an attractive force only from the very few other protons with which it is in close contact. Even though the strong force at its maximum is much larger than the electrostatic force, there wouldn't be enough attractive nuclear bonds for an all-proton nucleus to be stable. Because neutrons participate in the strong force

but exert no repulsive forces, **the neutrons provide the extra "glue" that holds the nucleus together.** In small nuclei, where most nucleons are in contact, one neutron per proton is sufficient for stability. Hence small nuclei have $N \approx Z$. But as the nucleus grows, the repulsive force increases faster than the binding energy. More neutrons are needed for stability, causing heavy nuclei to have $N > Z$.

43.4 The Shell Model

Figure 43.8 shows the potential energy of *two* interacting nucleons. To solve Schrödinger's equation for the nucleus, we would need to know the total potential energy of *all* interacting nucleon pairs within the nucleus, including both the strong force and the electrostatic force. This is far too complex to be a tractable problem.

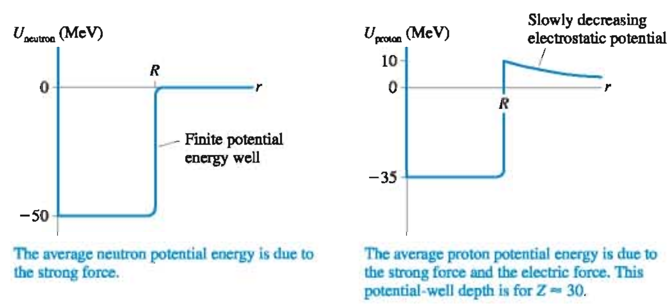
We faced a similar situation with multielectron atoms. Calculating an atom's exact potential energy is exceedingly complicated. To simplify the problem, we made a *model* of the atom in which each electron moves independently with an *average* potential energy due to the nucleus and all other electrons. That model, although not perfect, correctly predicted electron shells and explained the periodic table of the elements.

The **shell model** of the nucleus, using multielectron atoms as an analogy, was proposed in 1949 by Maria Goeppert-Mayer. The shell model considers each nucleon to move independently with an *average* potential energy due to the strong force of all the other nucleons. For the protons, we also have to include the electrostatic potential energy due to the other protons.

Maria Goeppert-Mayer shows her Nobel prize.

FIGURE 43.9 shows the average potential energy of a neutron and a proton. Here r is the distance from the center of the nucleus, not the nucleon–nucleon distance as it was in Figure 43.8. On average, a nucleon's interactions with neighboring nucleons is independent of the nucleon's position inside the nucleus; hence the constant potential energy inside the nucleus. You can see that, to a good approximation, a nucleon appears to be a particle in a finite potential well, a quantum-mechanics problem you learned how to deal with in Chapter 41.

FIGURE 43.9 The average potential energy of a neutron and a proton.

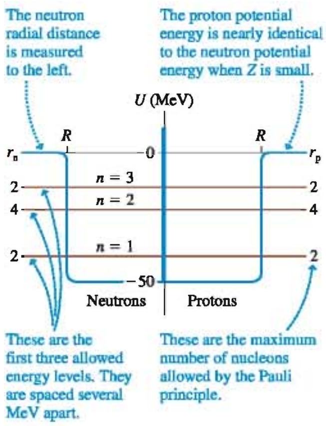


Three observations are worthwhile:

1. The depth of the neutron's potential-energy well is ≈ 50 MeV for all nuclei. The radius of the potential-energy well is the nuclear radius $R = r_0 A^{1/3}$.
2. For protons, the positive electrostatic potential energy "lifts" the potential-energy well. The lift varies from essentially none for very light elements to a significant fraction of the well depth for very heavy elements. The potential-energy shown in the figure would be appropriate for a nucleus with $Z \approx 30$.
3. Outside the nucleus, where the strong force has vanished, a proton's potential energy is $U = (Z - 1)e^2/4\pi\epsilon_0 r$ due to its electrostatic interaction with the $(Z - 1)$ other protons within the nucleus. This positive potential energy decreases slowly with increasing distance.

The task of quantum mechanics is to solve for the energy levels and wave functions of the nucleons in these potential-energy wells. Once the energy levels are found, we build up the nuclear state, just as we did with atoms, by placing all the nucleons in the lowest energy levels consistent with the Pauli principle. The Pauli principle affects nucleons, just as it did electrons, because they are spin-$\frac{1}{2}$ particles. Each energy level can hold only a certain number of spin-up particles and spin-down particles, depending on the quantum numbers. Additional nucleons have to go into higher energy levels.

FIGURE 43.10 The three lowest energy levels of a low-Z nucleus. The neutron energy levels are on the left, the proton energy levels on the right.



Low-*Z* Nuclei

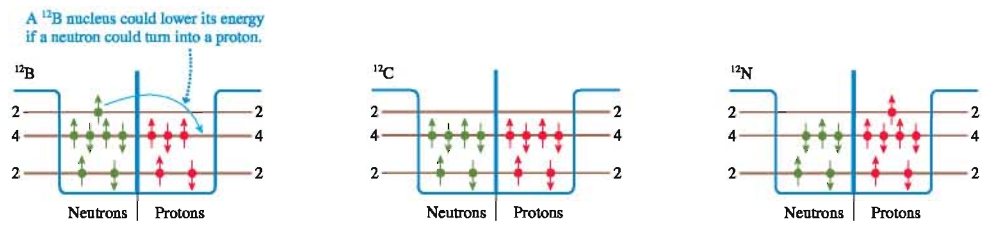
As an example, we'll consider the energy levels of low-Z nuclei ($Z < 8$). Because these nuclei have so few protons, we can use a reasonable approximation that neglects the electrostatic potential energy due to proton-proton repulsion and considers only the much larger nuclear potential energy. In that case, the proton and neutron potential-energy wells and energy levels are the same.

FIGURE 43.10 shows the three lowest energy levels and the maximum number of nucleons that the Pauli principle allows in each. Energy values vary from nucleus to nucleus, but the spacing between these levels is several MeV. It's customary to draw the proton and neutron potential-energy diagrams and energy levels back to back. Notice that the radial axis for the proton potential-energy well points to the right, while the radial axis for the neutron potential-energy well points to the left.

Let's apply this model to the $A = 12$ isobar. Recall that an isobar is a series of nuclei with the same total number of neutrons and protons. FIGURE 43.11 shows the energy-level diagrams of ^{12}B, ^{12}C, and ^{12}N. Look first at ^{12}C, a nucleus with six protons and six neutrons. You can see that exactly six protons are allowed in the $n = 1$ and $n = 2$ energy levels. Likewise for the six neutrons. Thus ^{12}C has a closed $n = 2$ proton shell and a closed $n = 2$ neutron shell.

NOTE ► Protons and neutrons are different particles, so the Pauli principle is not violated if a proton and a neutron have the same quantum numbers. ◄

FIGURE 43.11 The $A = 12$ isobar has to place 12 nucleons in the lowest available energy levels.



^{12}N has seven protons and five neutrons. The sixth proton fills the $n = 2$ proton shell, so the seventh proton has to go into the $n = 3$ energy level. The $n = 2$ neutron shell has one vacancy because there are only five neutrons. ^{12}B is just the opposite, with the seventh neutron in the $n = 3$ energy level. You can see from the diagrams that the ^{12}B and ^{12}N nuclei have significantly more energy—by several MeV—than ^{12}C.

In atoms, electrons in higher energy levels decay to lower energy levels by emitting a photon as the electron undergoes a quantum jump. That can't happen here because the higher-energy nucleon in ^{12}B is a neutron whereas the vacant lower energy level is that of a proton. But an analogous process could occur *if* a neutron could somehow turn into a proton. And that's exactly what happens! We'll explore the details in Section 43.6, but both ^{12}B and ^{12}N decay into ^{12}C in the process known as *beta decay.*

^{12}C is just one of three low-Z nuclei in which both the proton and neutron shells are full. The other two are ^4He (filling both $n = 1$ shells with $Z = 2$, $N = 2$) and ^{16}O (filling both $n = 3$ shells with $Z = 8$, $N = 8$). If the analogy with closed electron shells is valid, these nuclei should be more tightly bound than nuclei with neighboring values of A. And indeed, we've already noted that the curve of binding energy (Figure 43.6) has peaks at $A = 4$, 12, and 16. The shell model of the nucleus satisfactorily explains these peaks. Unfortunately, the shell model quickly becomes much more complex as we go beyond $n = 3$. Heavier nuclei do have closed shells, but there's no evidence for them in the curve of binding energy.

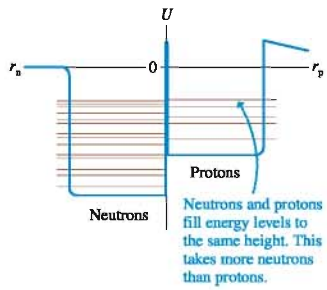
High-Z Nuclei

We can use the shell model to give a qualitative explanation for one more observation, although the details are beyond the scope of this text. FIGURE 43.12 shows the neutron and proton potential-energy wells of a high-Z nucleus. In a nucleus with many protons, the electrostatic potential energy lifts the proton potential-energy well higher than the neutron potential-energy well. Protons and neutrons now have a different set of energy levels.

As a nucleus is "built," by the addition of protons and neutrons, the proton energy well and the neutron energy well must fill to just about the same height. If there were neutrons in energy levels above vacant proton levels, the nucleus would lower its energy by using beta decay to change the neutron into a proton. Similarly, beta decay would change a proton into a neutron if there were a vacant neutron energy level beneath a filled proton level. **The net result of beta decay is to keep the filled levels on both sides at just about the same height.**

Because the neutron potential-energy well starts at a lower energy, *more neutron states* are available than proton states. Consequently, a high-Z nucleus will have more neutrons than protons. This conclusion is consistent with our observation in Figure 43.4 that $N > Z$ for heavy nuclei.

FIGURE 43.12 The proton energy levels are displaced upward in a high-Z nucleus.



Marie Curie.

43.5 Radiation and Radioactivity

Becquerel's 1896 discovery of "rays" from crystals of uranium prompted a burst of activity. Becquerel was soon joined in France by Marie Curie and Pierre Curie. They focused on isolating the element or elements responsible for the radiation and, in the process, discovered the element radium.

In England, J. J. Thomson and, especially, his student and protégé Ernest Rutherford worked to identify the unknown rays. Using combinations of electric and magnetic fields, much as Thomson had done in his investigations of cathode rays, they found three distinct types of radiation. Figure 43.13 shows the basic experimental procedure, and Table 43.3 on the next page summarizes the results.

FIGURE 43.13 Identifying radiation by its deflection in a magnetic field.

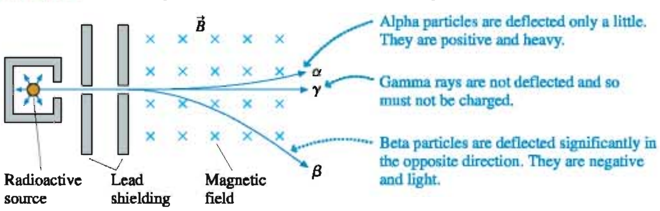


TABLE 43.3 Three types of radiation

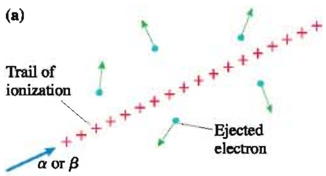
Radiation	Identification	Charge	Stopped by
Alpha, α	^{4}He nucleus	$+2e$	Sheet of paper
Beta, β	Electron	$-e$	Few mm of aluminum
Gamma, γ	High-energy photon	0	Many cm of lead

FIGURE 43.14 Alpha and beta particles create a trail of ionization as they pass through matter. This is the basis for the hydrogen bubble chamber.

(a)



(b)

Within a few years, as Rutherford and others deduced the basic structure of the atom, it became clear that these emissions of radiation were coming from the atomic nucleus. We now define *radioactivity* or *radioactive decay* to be the spontaneous emission of particles or high-energy photons from unstable nuclei as they decay from higher-energy to lower-energy states. Radioactivity has nothing to do with the orbiting valence electrons.

NOTE ▶ The term "radiation" merely means something that is *radiated outward,* similar to the word "radial." Electromagnetic waves are often called "electromagnetic radiation." Infrared waves from a hot object are referred to as "thermal radiation." Thus it was no surprise that these new "rays" were also called radiation. Unfortunately, the general public has come to associate the word "radiation" with *nuclear radiation,* something to be feared. It is important, when you use the term, to be sure you're not conveying a wrong impression to a listener or a reader. ◀

Ionizing Radiation

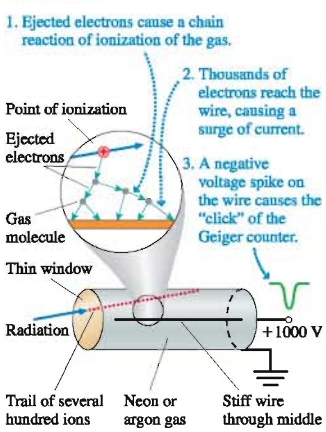
Electromagnetic waves, from microwaves through ultraviolet radiation, are absorbed by matter. The absorbed energy increases an object's thermal energy and its temperature, which is why objects sitting in the sun get warm.

In contrast to visible-light photon energies of a few eV, the energies of the alpha and beta particles and the gamma-ray photons of nuclear decay are typically in the range 0.1–10 MeV, a factor of roughly 10^6 larger. These energies are much larger than the ionization energies of atoms and molecules. Rather than simply being absorbed and increasing an object's thermal energy, nuclear radiation *ionizes* matter and *breaks* molecular bonds. Nuclear radiation (and also x rays, which behave much the same in matter) is called **ionizing radiation.**

An alpha or beta particle traveling through matter creates a trail of ionization, as shown in FIGURE 43.14a. Because the ionization energy of an atom is ≈ 10 eV, a particle with 1 MeV of kinetic energy can ionize $\approx 100{,}000$ atoms or molecules before finally stopping. The low-mass electrons are kicked sideways, but the much more massive positive ions barely move and form the trail. This behavior is the basis for the *cloud chamber* and the *hydrogen bubble chamber,* where microscopic water droplets or hydrogen gas bubbles coalesce around the positive ions to make the trail visible. FIGURE 43.14b is a picture of the ionization trails of high-energy particles in a bubble chamber. The curvature of the trajectories is due to a magnetic field.

Ionization is also the basis for the **Geiger counter,** one of the most well-known detectors of nuclear radiation. FIGURE 43.15 shows how a Geiger counter works. The important thing to remember is that a Geiger counter detects only *ionizing radiation.*

FIGURE 43.15 A Geiger counter.



Ionizing radiation damages materials. Ions drive chemical reactions that wouldn't otherwise occur. Broken molecular bonds alter the workings of molecular machinery, especially in large biological molecules. It is through these mechanisms—ionization and bond breaking—that nuclear radiation can cause mutations or tumors. We'll look at the biological issues in Section 43.7.

NOTE ▶ Ionizing radiation causes structural damage to materials, but **irradiated objects do not become radioactive.** Ionization drives chemical processes involving the electrons. An object could become radioactive only if its nuclei were somehow changed, and that does not happen. ◀

STOP TO THINK 43.3 A very bright spotlight shines on a Geiger counter. Does it click?

Nuclear Decay and Half-Lives

Rutherford was the first to find that the number of radioactive atoms in a sample decreases exponentially with time. This is the expected time dependence if the decay is a *random process*. But to say that a process is random doesn't mean there are no patterns. Tossing a coin is a random process because you can't predict what one coin will do. Even so, if you tossed 1000 coins, you'd certainly find very nearly 500 heads and 500 tails. Nuclear decay is similar.

Let r be the probability that one particular nucleus will decay in the next 1 s by emitting an alpha or beta particle or a gamma-ray photon. For example, $r = 0.010\ \text{s}^{-1}$ means that a nucleus has a 1% chance of decay in the next second. Notice that r, which is called the **decay rate,** has units s^{-1}, making it a *rate*.

The probability that a nucleus decays during the small interval of time Δt is

$$\text{Prob(in } \Delta t) = r\Delta t \qquad (43.7)$$

For example, a nucleus with $r = 0.010\ \text{s}^{-1}$ has a 0.1% chance of decay (Prob = 0.001) during a 0.1 s interval. If there are N independent nuclei, the number of nuclei expected to decay during Δt is

$$\text{number of decays} = N \times \text{probability of decay} = rN\Delta t \qquad (43.8)$$

This is like saying you expect 500 heads when tossing 1000 coins, each coin with a 50% probability of landing heads up.

Each decay *decreases* the number of radioactive nuclei in the sample, hence the change in the number of radioactive nuclei during Δt is

$$\Delta N = -rN\Delta t \qquad (43.9)$$

The negative sign shows that N, the number of nuclei, decreases due to the decays. Finally, if we let $\Delta t \to dt$, Equation 43.9 becomes

$$\frac{dN}{dt} = -rN \qquad (43.10)$$

The *rate of change* in the number of radioactive nuclei depends both on the decay rate (a higher probability of decay per second means more decays per second) and on the number of radioactive nuclei present (more nuclei means that more are available to decay). And dN/dt is negative because N is decreasing.

Equation 43.10 is the same equation we solved in Chapter 32, with different symbols, for the voltage decay in an RC circuit. First, we separate the variables onto opposite sides of the equation:

$$\frac{dN}{N} = -r\,dt \qquad (43.11)$$

We need to integrate this equation, starting from $N = N_0$ nuclei at $t = 0$. Thus

$$\int_{N_0}^{N} \frac{dN}{N} = -r\int_0^t dt \qquad (43.12)$$

By carrying out the integrations, we find

$$\ln N - \ln N_0 = \ln\left(\frac{N}{N_0}\right) = -rt \qquad (43.13)$$

We can now solve for N by taking the exponential of both sides and multiplying by N_0. The result is

$$N = N_0 e^{-rt} \tag{43.14}$$

Equation 43.13 predicts that the number of radioactive nuclei will decrease exponentially, a prediction that has been borne out in countless experiments during the last hundred years.

It is useful to define the **time constant** τ as

$$\tau = \frac{1}{r}$$

With this definition, Equation 43.13 becomes

$$\boxed{N = N_0 e^{-t/\tau}} \tag{43.15}$$

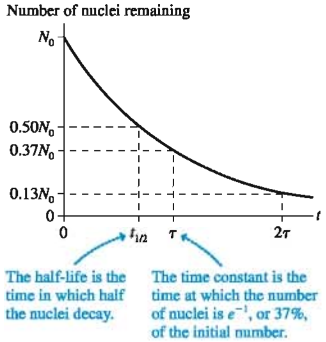


FIGURE 43.16 The number of radioactive atoms decreases exponentially with time.

FIGURE 43.16 shows the decrease of N with time. The number of radioactive nuclei decreases from N_0 at $t = 0$ to $e^{-1}N_0 = 0.368N_0$ at time $t = \tau$. In practical terms, the number decreases by roughly two-thirds during one time constant.

NOTE ▶ An important aspect of exponential decay is that you can choose any instant you wish to be $t = 0$. The number of radioactive nuclei present at that instant is N_0. If at one instant you have 10,000 radioactive nuclei whose time constant is $\tau = 10$ min, you'll have roughly 3680 nuclei 10 min later. The fact that you may have had more than 10,000 nuclei earlier isn't relevant. ◀

Equation 43.14 is useful in the theoretical sense that we can relate τ directly to the probability of decay. But in practice, it's much easier to measure the time at which half of a sample has decayed than the time at which 36.8% has decayed. Let's define the **half-life** $t_{1/2}$ as the time interval in which half of a sample of radioactive atoms decays. The half-life is shown in Figure 43.16.

The half-life is easily related to the time constant τ because we know, by definition, that $N = \frac{1}{2}N_0$ at $t = t_{1/2}$. Thus, according to Equation 43.15,

$$\frac{N_0}{2} = N_0 e^{-t_{1/2}/\tau} \tag{43.16}$$

The N_0 cancels, and we can then take the natural logarithm of both sides to find

$$\ln\left(\frac{1}{2}\right) = -\ln 2 = -\frac{t_{1/2}}{\tau} \tag{43.17}$$

With one final rearrangement we have

$$t_{1/2} = \tau \ln 2 = 0.693\tau \tag{43.18}$$

We'll leave it as a homework problem for you to show that Equation 43.15 can be written in terms of the half-life as

$$\boxed{N = N_0\left(\frac{1}{2}\right)^{t/t_{1/2}}} \tag{43.19}$$

Thus $N = N_0/2$ at $t = t_{1/2}$, $N = N_0/4$ at $t = 2t_{1/2}$, $N = N_0/8$ at $t = 3t_{1/2}$, and so on. **No matter how many nuclei there are, the number decays by half during the next half-life.**

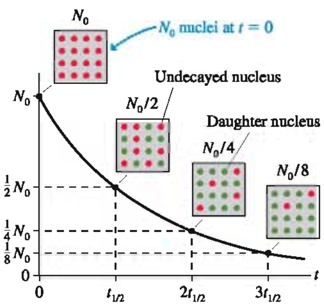
NOTE ▶ Half the nuclei decay during one half-life, but don't fall into the trap of thinking that all will have decayed after two half-lives. ◀

FIGURE 43.17 shows the half-life graphically. This figure also conveys two other important ideas:

1. Nuclei don't vanish when they decay. The decayed nuclei have merely become some other kind of nuclei.
2. The decay process is random. We can predict that half the nuclei will decay in one half-life, but we can't predict which ones.

Each radioactive isotope, such as ^{14}C, has its own half-life. That half-life doesn't change with time as a sample decays. If you've flipped a coin 10 times and, against all odds, seen 10 heads, you may feel that a tail is overdue. Nonetheless, the probability that the next flip will be a head is still 50%. After 10 half-lives have gone by, $(1/2)^{10} = 1/1024$ of a radioactive sample is still there. There was nothing special or distinctive about these nuclei, and, despite their longevity, each remaining nucleus has exactly a 50% chance of decay during the next half-life.

FIGURE 43.17 Half the nuclei decay during each half-life.



EXAMPLE 43.2 The decay of iodine

The iodine isotope ^{131}I, which has an eight-day half-life, is used in nuclear medicine. A sample of ^{131}I containing 2.00×10^{12} atoms is created in a nuclear reactor.

a. How many ^{131}I atoms remain 36 hours later when the sample is delivered to a hospital?
b. The sample is constantly getting weaker, but it remains usable as long as there are at least 5.0×10^{11} ^{131}I atoms. What is the maximum delay before the sample is no longer usable?

MODEL The number of ^{131}I atoms decays exponentially.

SOLVE a. The half-life is $t_{1/2} = 8$ days $= 192$ hr. After 36 hr have elapsed,

$$N = (2.00 \times 10^{12})\left(\frac{1}{2}\right)^{36/192} = 1.76 \times 10^{12} \text{ nuclei}$$

b. The time after creation at which 5.0×10^{11} ^{131}I atoms remain is given by

$$5.0 \times 10^{11} = 0.50 \times 10^{12} = (2.0 \times 10^{12})\left(\frac{1}{2}\right)^{t/8\text{ days}}$$

To solve for t, we first write this as

$$\frac{0.50}{2.00} = 0.25 = \left(\frac{1}{2}\right)^{t/8\text{ days}}$$

Now we take the logarithm of both sides. Either natural logarithms or base-10 logarithms can be used, but we'll use natural logarithms:

$$\ln(0.25) = -1.39 = \frac{t}{t_{1/2}}\ln(0.5) = -0.693\frac{t}{t_{1/2}}$$

Solving for t gives

$$t = 2.00t_{1/2} = 16 \text{ days}$$

ASSESS The weakest usable sample is one-quarter of the initial sample. You saw in Figure 43.17 that a radioactive sample decays to one-quarter of its initial number in 2 half-lives.

Activity

The **activity** R of a radioactive sample is the number of decays per second. This is simply the absolute value of dN/dt, or

$$R = \left|\frac{dN}{dt}\right| = rN = rN_0e^{-t/\tau} = R_0e^{-t/\tau} = R_0\left(\frac{1}{2}\right)^{t/t_{1/2}} \tag{43.20}$$

where $R_0 = rN_0$ is the activity at $t = 0$. The activity of a sample decreases exponentially along with the number of remaining nuclei.

The SI unit of activity is the **becquerel,** defined as

$$1 \text{ becquerel} = 1 \text{ Bq} \equiv 1 \text{ decay/s or } 1 \text{ s}^{-1}$$

An older unit of activity, but one that continues in widespread use, is the **curie.** The curie was originally defined as the activity of 1 g of radium. Today, the conversion factor is

$$1 \text{ curie} = 1 \text{ Ci} \equiv 3.7 \times 10^{10} \text{ Bq}$$

One curie is a substantial activity. The radioactive samples used in laboratory experiments are typically $\approx 1\ \mu\text{Ci}$, or, equivalently, $\approx 40{,}000$ Bq. These samples can be handled with only minor precautions. Larger sources of radioactivity require lead shielding and special precautions to prevent exposure to high levels of radiation.

EXAMPLE 43.3 A laboratory source

The isotope ^{137}Cs is a standard laboratory source of gamma rays. The half-life of ^{137}Cs is 30 years.

a. How many ^{137}Cs atoms are in a 5.0 μCi source?
b. What is the activity of the source 10 years later?

MODEL The number of ^{137}Cs atoms decays exponentially.

SOLVE a. The number of atoms can be found from $N_0 = R_0/r$. The activity in SI units is

$$R = 5.0 \times 10^{-6}\ \text{Ci} \times \frac{3.7 \times 10^{10}\ \text{Bq}}{1\ \text{Ci}} = 1.85 \times 10^5\ \text{Bq}$$

To find the decay rate, first convert the half-life to seconds:

$$t_{1/2} = 30\ \text{years} \times \frac{3.15 \times 10^7\ \text{s}}{1\ \text{year}} = 9.45 \times 10^8\ \text{s}$$

Then

$$r = \frac{1}{\tau} = \frac{\ln 2}{t_{1/2}} = 7.33 \times 10^{-10}\ \text{s}^{-1}$$

Thus the number of ^{137}Cs atoms is

$$N_0 = \frac{R_0}{r} = \frac{1.85 \times 10^5\ \text{Bq}}{7.33 \times 10^{-10}\ \text{s}^{-1}} = 2.5 \times 10^{14}\ \text{atoms}$$

b. The activity decreases exponentially, just like the number of nuclei. After 10 years,

$$R = R_0\left(\frac{1}{2}\right)^{t/t_{1/2}} = (5.0\ \mu\text{Ci})\left(\frac{1}{2}\right)^{10/30} = 4.0\ \mu\text{Ci}$$

ASSESS Although N_0 is a very large number, it is a very small fraction ($\approx 10^{-10}$) of a mole. The sample is about 60 ng (nanograms) of ^{137}Cs.

The technique known as *carbon dating* uses the radioactive decay of the naturally occuring carbon isotope ^{14}C to determine the age of fossils and archeological artifacts.

Radioactive Dating

Many geological and archeological samples can be dated by measuring the decays of naturally occurring radioactive isotopes. Because we have no way to know N_0, the initial number of radioactive nuclei, radioactive dating depends on the use of ratios.

The most well-known dating technique is carbon dating. The carbon isotope ^{14}C has a half-life of 5730 years, so any ^{14}C present when the earth formed 4.5 billion years ago would long since have decayed away. Nonetheless, ^{14}C is present in atmospheric carbon dioxide because high-energy cosmic rays collide with gas molecules high in the atmosphere. These cosmic rays are energetic enough to create ^{14}C nuclei from nuclear reactions with nitrogen and oxygen nuclei. The creation and decay of ^{14}C have reached a steady state in which the $^{14}\text{C}/^{12}\text{C}$ ratio is 1.3×10^{-12}. That is, atmospheric carbon dioxide has ^{14}C at the concentration of 1.3 parts per trillion. As small as this is, it's easily measured by modern chemical techniques.

All living organisms constantly exchange carbon dioxide with the atmosphere, so the $^{14}\text{C}/^{12}\text{C}$ ratio in living organisms is also 1.3×10^{-12}. When an organism dies, the ^{14}C in its tissue begins to decay and no new ^{14}C is added. Objects are dated by comparing the measured $^{14}\text{C}/^{12}\text{C}$ ratio to the 1.3×10^{-12} value of living material.

Carbon dating is used to date skeletons, wood, paper, fur, food material, and anything else made of organic matter. It is quite accurate for ages to about 15,000 years, roughly three half-lives of ^{14}C. Beyond that, the difficulty of measuring such a small ratio and some uncertainties about the cosmic ray flux in the past combine to decrease the accuracy. Even so, items are dated to about 50,000 years with a fair degree of reliability.

Other isotopes with longer half-lives are used to date geological samples. Potassium-argon dating, using ^{40}K with a half-life of 1.25 billion years, is especially useful for dating rocks of volcanic origin.

EXAMPLE 43.4 Carbon dating

Archeologists excavating an ancient hunters' camp have recovered a 5.0 g piece of charcoal from a fireplace. Measurements on the sample find that the ^{14}C activity is 0.35 Bq. What is the approximate age of the camp?

MODEL Charcoal, from burning wood, is almost pure carbon. The number of ^{14}C atoms in the wood has decayed exponentially since the branch fell off a tree. Because wood rots, it is reasonable to assume that there was no significant delay between when the branch fell off the tree and the hunters burned it.

SOLVE The $^{14}\text{C}/^{12}\text{C}$ ratio was 1.3×10^{-12} when the branch fell from the tree. We first need to determine the present ratio, then use the known ^{14}C half-life $t_{1/2} = 5730$ years to calculate the time needed to reach the present ratio. The number of ordinary ^{12}C nuclei in the sample is

$$N(^{12}\text{C}) = \left(\frac{5.0\text{ g}}{12\text{ g/mol}}\right)6.02 \times 10^{23}\text{ atoms/mol}$$
$$= 2.5 \times 10^{23}\text{ nuclei}$$

The number of ^{14}C nuclei can be found from the activity to be $N(^{14}\text{C}) = R/r$, but we need to determine the ^{14}C decay rate r. After converting the half-life to seconds, $t_{1/2} = 5730\text{ years} = 1.807 \times 10^{11}$ s, we can compute

$$r = \frac{1}{\tau} = \frac{1}{t_{1/2}/\ln 2} = 3.84 \times 10^{-12}\text{ s}^{-1}$$

Thus

$$N(^{14}\text{C}) = \frac{R}{r} = \frac{0.35\text{ Bq}}{3.84 \times 10^{-12}\text{ s}^{-1}} = 9.1 \times 10^{10}\text{ nuclei}$$

and the present $^{14}\text{C}/^{12}\text{C}$ ratio is $N(^{14}\text{C})/N(^{12}\text{C}) = 0.36 \times 10^{-12}$. Because this ratio has been decaying with a half-life of 5730 years, the time needed to reach the present ratio is found from

$$0.36 \times 10^{-12} = 1.3 \times 10^{-12}\left(\frac{1}{2}\right)^{t/t_{1/2}}$$

To solve for t, we first write this as

$$\frac{0.36}{1.3} = 0.277 = \left(\frac{1}{2}\right)^{t/t_{1/2}}$$

Now we take the logarithm of both sides:

$$\ln(0.277) = -1.28 = \frac{t}{t_{1/2}}\ln(0.5) = -0.693\frac{t}{t_{1/2}}$$

Thus the age of the hunters' camp is

$$t = 1.85t_{1/2} = 10{,}600\text{ years}$$

ASSESS This is a realistic example of how radioactive dating is done.

STOP TO THINK 43.4 A sample starts with 1000 radioactive atoms. How many half-lives have elapsed when 750 atoms have decayed?

a. 0.25
b. 1.5
c. 2.0
d. 2.5

43.6 Nuclear Decay Mechanisms

This section will look in more detail at the mechanisms of the three types of radioactive decay.

ActivPhysics ONLINE 19.4

Alpha Decay

An alpha particle, symbolized as α, is a ^{4}He nucleus, a strongly bound system of two protons and two neutrons. An unstable nucleus that ejects an alpha particle will lose two protons and two neutrons, so we can write the decay as

$$^{A}\text{X}_{Z} \rightarrow {}^{A-4}\text{Y}_{Z-2} + \alpha + \text{energy} \tag{43.21}$$

FIGURE 43.18 Alpha decay.

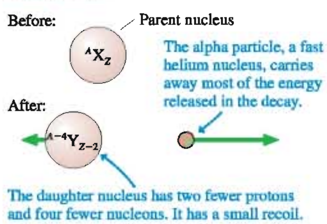


FIGURE 43.18 shows the alpha-decay process. The original nucleus X is called the **parent nucleus,** and the decay-product nucleus Y is the **daughter nucleus.** This reaction can occur only when the mass of the parent nucleus is greater than the mass of the daughter nucleus plus the mass of an alpha particle. This requirement is met for heavy,

high-Z nuclei well above the maximum on the Figure 43.6 curve of binding energy. It is energetically favorable for these nuclei to eject an alpha particle because the daughter nucleus is more tightly bound than the parent nucleus.

Although the mass requirement is based on the nuclear masses, we can express it—as we did the binding energy equation—in terms of atomic masses. The energy released in an alpha decay, essentially all of which goes into the alpha particle's kinetic energy, is

$$\Delta E \approx K_\alpha = (m_X - m_Y - m_{He})c^2 \tag{43.22}$$

EXAMPLE 43.5 Alpha decay of uranium

The uranium isotope ^{238}U undergoes alpha decay to ^{234}Th. The atomic masses are 238.0508 u for ^{238}U and 234.0436 u for ^{234}Th. What is the kinetic energy, in MeV, of the alpha particle?

MODEL Essentially all of the energy release ΔE goes into the alpha particle's kinetic energy.

SOLVE The atomic mass of helium is 4.0026 u. Thus

$$K_\alpha = (238.0508\text{ u} - 234.0436\text{ u} - 4.0026\text{ u})c^2$$

$$= \left(0.0046\text{ u} \times \frac{931.5\text{ MeV}/c^2}{1\text{ u}}\right)c^2 = 4.3\text{ MeV}$$

ASSESS This is a typical alpha-particle energy. Notice how the c^2 canceled from the calculation so that we never had to evaluate c^2.

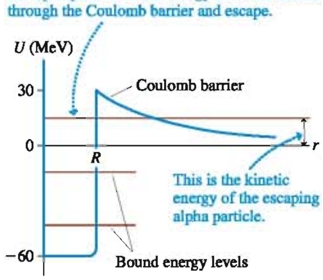

FIGURE 43.19 The potential-energy diagram of an alpha particle in the parent nucleus.

Alpha decay is a purely quantum-mechanical effect. **FIGURE 43.19** shows the potential energy of an alpha particle, where the ^{4}He nucleus of an alpha particle is so tightly bound that we can think of it as existing "prepackaged" inside the parent nucleus. Both the depth of the energy well and the height of the Coulomb barrier are twice those of a proton because the charge of an α particle is $2e$.

Because of the high Coulomb barrier (alpha decay occurs only in high-Z nuclei), there may be one or more allowed energy levels with $E > 0$. Energy levels with $E < 0$ are completely bound, but an alpha particle in an energy level with $E > 0$ can *tunnel* through the Coulomb barrier and escape. That is exactly how alpha decay occurs.

Energy must be conserved, so the kinetic energy of the escaping α particle is the height of the energy level above $E = 0$. That is, potential energy is transformed into kinetic energy as the particle escapes. Notice that the width of the barrier decreases as E increases. The tunneling probability depends very sensitively on the barrier width, as you learned in conjunction with the scanning tunneling microscope. Thus an alpha particle in a higher energy level should have a *shorter half-life* and escape with *more kinetic energy.* The full analysis is beyond the scope of this text, but this prediction is in excellent agreement with measured energies and half-lives.

Beta Decay

Beta decay was initially associated with the emission of an electron e^-, the beta particle. It was later discovered that some nuclei can undergo beta decay by emitting a positron e^+, the antiparticle of the electron, although this decay mode is not as common. A positron is identical to an electron except that it has a positive charge. To be precise, the emission of an electron is called *beta-minus decay* and the emission of a positron is *beta-plus decay.*

A typical example of beta-minus decay occurs in the carbon isotope ^{14}C, which undergoes the beta-decay process $^{14}C \rightarrow {}^{14}N + e^-$. Carbon has $Z = 6$ and nitrogen has $Z = 7$. Because Z increases by 1 but A doesn't change, it appears that a neutron within the nucleus has changed itself into a proton and an electron. That is, the basic beta-minus decay process appears to be

$$n \rightarrow p^+ + e^- \tag{43.23}$$

The electron is ejected from the nucleus but the proton is not. Thus the decay process, shown in FIGURE 43.20a, is

$$^{A}X_{Z} \rightarrow {}^{A}Y_{Z+1} + e^{-} + \text{energy} \quad \text{(beta-minus decay)} \tag{43.24}$$

Indeed, a free neutron turns out *not* to be a stable particle. It decays with a half-life of approximately 10 min into a proton and an electron. This decay is energetically allowed because $m_n > m_p + m_e$. Furthermore, it conserves charge.

Whether a neutron *within* a nucleus can decay depends not only on the masses of the neutron and proton but also on the masses of the parent and daughter nuclei, because energy has to be conserved for the entire nuclear system. **Beta decay occurs only if $m_X > m_Y$.** ^{14}C can undergo beta decay to ^{14}N because $m(^{14}C) > m(^{14}N)$. But $m(^{12}C) < m(^{12}N)$, so ^{12}C is stable and its neutrons cannot decay.

Beta-plus decay is the conversion of a proton into a neutron and a positron:

$$p^{+} \rightarrow n + e^{+} \tag{43.25}$$

The full decay process, shown in FIGURE 43.20b, is

$$^{A}X_{Z} \rightarrow {}^{A}Y_{Z-1} + e^{+} + \text{energy} \quad \text{(beta-plus decay)} \tag{43.26}$$

Beta-plus decay does *not* happen for a free proton because $m_p < m_n$. It *can* happen within a nucleus as long as energy is conserved for the entire nuclear system.

In our earlier discussion of Figure 43.11 we noted that the ^{12}B and ^{12}N nuclei could reach a lower energy state if a proton could change into a neutron, and vice versa. Now we see that such a change can occur if the energy conditions are favorable. And, indeed, ^{12}B undergoes beta-minus decay to ^{12}C while ^{12}N undergoes beta-plus decay to ^{12}C.

In general, beta decay is a process used by nuclei with too many neutrons or too many protons in order to move closer to the line of stability in Figure 43.4.

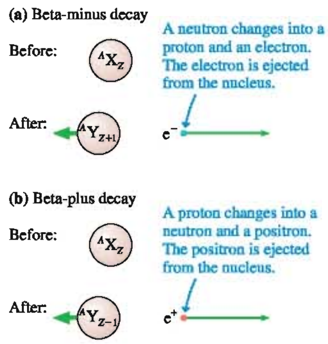
NOTE ▶ The electron emitted in beta-minus decay has nothing to do with the atom's orbital electrons. The beta particle is created in the nucleus and ejected directly from the nucleus when a neutron is transformed into a proton and an electron. ◀

A third form of beta decay occurs in some nuclei that have too many protons but not enough mass to undergo beta-plus decay. In this case, a proton changes into a neutron by "capturing" an electron from the innermost shell of orbiting electrons (an $n = 1$ electron). The process is

$$p^{+} + \text{orbital } e^{-} \rightarrow n \tag{43.27}$$

This form of beta decay is called **electron capture,** abbreviated EC. The net result, $^{A}X_{Z} \rightarrow {}^{A}Y_{Z-1}$, is the same as beta-plus decay but without the emission of a positron. Electron capture is the only nuclear decay mechanism that involves the orbital electrons.

FIGURE 43.20 Beta decay.



The Weak Interaction

We've presented beta decay as if it were perfectly normal for one kind of matter to change spontaneously into a completely different kind of matter. For example, it would be energetically favorable for a large truck to spontaneously turn into a Cadillac and a VW Beetle, ejecting the Beetle at high speed. But it doesn't happen.

Once you stop to think of it, the process $n \rightarrow p^{+} + e^{-}$ seems ludicrous, not because it violates mass-energy conservation but because we have no idea *how* a

The Super Kamiokande neutrino detector in Japan looks for the neutrinos emitted from nuclear fusion reactions in the core of the sun.

neutron could turn into a proton. Alpha decay may be a strange process because tunneling in general goes against our commonsense notions, but it is a perfectly ordinary quantum-mechanical process. Now we're suggesting that one of the basic building blocks of matter can somehow morph into a different basic building block.

To make matters more confusing, measurements in the 1930s found that beta decay didn't seem to conserve either energy or momentum. Faced with these difficulties, the Italian physicist Enrico Fermi made two bold suggestions:

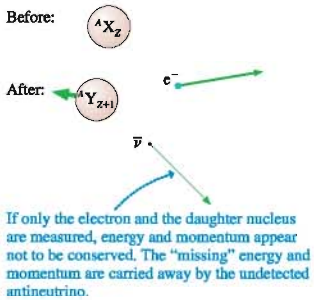
1. A previously unknown fundamental force of nature is responsible for beta decay. This force, which has come to be known as the **weak interaction,** has the ability to turn a neutron into a proton, and vice versa.
2. The beta-decay process emits a particle that, at that time, had not been detected. This new particle has to be electrically neutral, in order to conserve charge, and it has to be much less massive than an electron. Fermi called it the **neutrino,** meaning "little neutral one." Energy and momentum really are conserved, but the neutrino carries away some of the energy and momentum of the decaying nucleus. Thus experiments that detect only the electron seem to violate conservation laws.

The neutrino is represented by the symbol ν, a lowercase Greek nu. The beta-decay processes that Fermi proposed are

$$\begin{aligned} n &\rightarrow p^+ + e^- + \bar{\nu} \\ p^+ &\rightarrow n + e^+ + \nu \end{aligned} \tag{43.28}$$

The symbol $\bar{\nu}$ is an *antineutrino,* although the reason one is a neutrino and the other an antineutrino need not concern us here. FIGURE 43.21 shows that the electron and antineutrino (or positron and neutrino) *share* the energy released in the decay.

FIGURE 43.21 A more accurate picture of beta decay includes neutrinos.



The neutrino interacts with matter so weakly that a neutrino can pass straight through the earth with only a very slight chance of a collision. Thousands of neutrinos created by nuclear fusion reactions in the core of the sun are passing through your body every second. Neutrino interactions are so rare that the first laboratory detection did not occur until 1956, over 20 years after Fermi's proposal.

It was initially thought that the neutrino had not only zero charge but also zero mass. However, experiments within the last few years have shown that the neutrino mass, although very tiny, is not zero. The best current evidence suggests a mass about one-millionth the mass of an electron. Experiments now under way will attempt to determine a more accurate value. The result will have far more importance than simply understanding beta decay. Neutrinos are the most numerous of all particles in the universe, so it may turn out that the neutrino mass has cosmological significance for the evolution of the universe.

EXAMPLE 43.6 Beta decay of ^{14}C

How much energy is released in the beta-minus decay of ^{14}C?

MODEL The decay is $^{14}C \rightarrow {}^{14}N + e^- + \bar{\nu}$.

SOLVE In Appendix C we find $m(^{14}C) = 14.003242$ u and $m(^{14}N) = 14.003074$ u. The mass difference is a mere 0.000168 u, but this is the mass that is converted into the kinetic energy of the escaping particles. The energy released is

$$E = (\Delta m)c^2 = (0.000168\text{ u}) \times (931.5\text{ MeV/u}) = 0.156\text{ MeV}$$

ASSESS This energy is shared between the electron and the antineutrino.

Gamma Decay

Gamma decay is the easiest form of nuclear decay to understand. You learned that an atomic system can emit a photon with $E_{photon} = \Delta E_{atom}$ when an electron undergoes a quantum jump from an excited energy level to a lower energy level. Nuclei are no different. A proton or a neutron in an excited nuclear state, such as the one shown in FIGURE 43.22, can undergo a quantum jump to a lower-energy state by emitting a high-energy photon. This is the gamma-decay process.

The spacing between atomic energy levels is only a few eV. Nuclear energy levels, by contrast, are typically 1 MeV apart. Hence gamma-ray photons have $E_{gamma} \approx 1$ MeV. Photons with this much energy have tremendous penetrating power and deposit an extremely large amount of energy at the point where they are finally absorbed.

Nuclei left to themselves are usually in their ground states and thus cannot emit gamma-ray photons. However, alpha and beta decay often leave the daughter nucleus in an excited nuclear state, so gamma emission is usually found to accompany alpha and beta emission.

The cesium isotope ^{137}Cs is a good example. We noted earlier that ^{137}Cs is used as a laboratory source of gamma rays. Actually, ^{137}Cs undergoes beta-minus decay to ^{137}Ba. FIGURE 43.23 shows the full process. A ^{137}Cs nucleus undergoes beta-minus decay by emitting an electron and an antineutrino, which share between them a total energy of 0.51 MeV. The half-life for this process is 30 years. This leaves the daughter ^{137}Ba nucleus in an excited state 0.66 MeV above the ground state. The excited Ba nucleus then decays within a few seconds to the ground state by emitting a 0.66 MeV gamma-ray photon. Thus a ^{137}Cs sample *is* a source of gamma-ray photons, but the photons are actually emitted by barium nuclei rather than cesium nuclei.

FIGURE 43.22 Gamma decay.

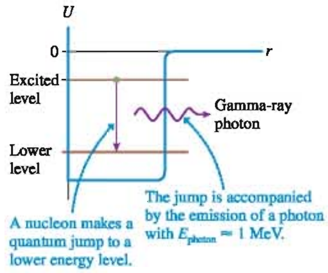


FIGURE 43.23 The decay of ^{137}Cs involves both beta and gamma decay.

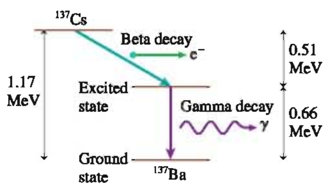


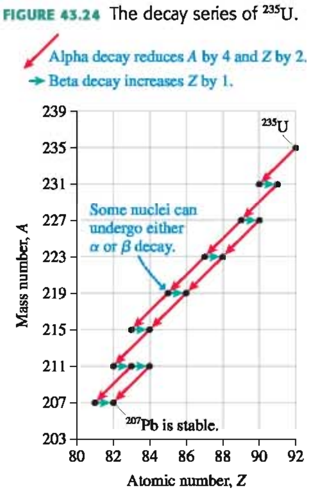
Decay Series

A radioactive nucleus decays into a daughter nucleus. In many cases, the daughter nucleus is also radioactive and decays to produce its own daughter nucleus. The process continues until reaching a daughter nucleus that is stable. The sequence of isotopes, starting with the original unstable isotope and ending with the stable isotope, is called a **decay series.**

Decay series are especially important for very heavy nuclei. As an example, FIGURE 43.24 shows the decay series of ^{235}U, an isotope of uranium with a 700-million-year half-life. This is a very long time, but it is only about 15% the age of the earth, thus most (but not all) of the ^{235}U nuclei present when the earth was formed have now decayed. There are many unstable nuclei along the way, but all ^{235}U nuclei eventually end as the ^{207}Pb isotope of lead, a stable nucleus.

Notice that some nuclei can decay by either alpha *or* beta decay. Thus there are a variety of paths that a decay can follow, but they all end at the same point.

FIGURE 43.24 The decay series of ^{235}U.



STOP TO THINK 43.5 The cobalt isotope ^{60}Co ($Z = 27$) decays to the nickel isotope ^{60}Ni ($Z = 28$). The decay process is

a. Alpha decay. b. Beta-minus decay. c. Beta-plus decay.
d. Electron capture. e. Gamma decay.

43.7 Biological Applications of Nuclear Physics

Nuclear physics has brought both peril and promise to society. Radiation can cause tumors, but it also can be used to cure some cancers. This section is a brief survey of medical and biological applications of nuclear physics.

Radiation Dose

Nuclear radiation, which is ionizing radiation, disrupts a cell's machinery by altering and damaging the biological molecules. The consequences of this disruption vary from genetic mutations to uncontrolled cell multiplication (i.e., tumors) to cell death.

Beta and gamma radiation can penetrate the entire body and damage internal organs. Alpha radiation has less penetrating ability, but it deposits all its energy in a very small, localized volume. Internal organs are usually safe from alpha radiation, but the skin is very susceptible, as are the lungs if radioactive dust is inhaled.

Biological effects of radiation depend on two factors. The first is the physical factor of how much energy is absorbed by the body. The second is the biological factor of how tissue reacts to different forms of radiation.

The **absorbed dose** of radiation is the energy of ionizing radiation absorbed per kilogram of tissue. The SI unit of absorbed dose is the **gray,** abbreviated Gy. It is defined as

$$1 \text{ gray} = 1 \text{ Gy} \equiv 1.00 \text{ J/kg of absorbed energy}$$

The absorbed dose depends only on the energy absorbed, not at all on the type of radiation or on what the absorbing material is.

Biologists and biophysicists have found that a 1 Gy dose of gamma rays and a 1 Gy dose of alpha particles have different biological consequences. To account for such differences, the **relative biological effectiveness** (RBE) is defined as the biological effect of a given dose relative to the biological effect of an equal dose of x rays.

TABLE 43.4 Relative biological effectiveness of radiation

Radiation type	RBE
X rays	1
Gamma rays	1
Beta particles	1–2
Alpha particles	10–20

Table 43.4 shows the relative biological effectiveness of different forms of radiation. Larger values correspond to larger biological effects. Alpha and beta radiation have a range of values because the biological effect varies with the energy of the particle. Alpha radiation has the largest RBE because the energy is deposited in the smallest volume.

The product of the absorbed dose with the RBE is called the **dose equivalent.** Dose equivalent is measured in **sieverts,** abbreviated Sv. To be precise,

$$\text{dose equivalent in Sv} = \text{absorbed dose in Gy} \times \text{RBE}$$

1 Sv of radiation produces the same biological damage regardless of the type of radiation. An older but still widely used unit for dose equivalent is the **rem,** defined as 1 rem = 0.010 Sv. Small radiation doses are measured in millisievert (mSv) or millirem (mrem).

EXAMPLE 43.7 Radiation exposure

A 75 kg laboratory technician working with the radioactive isotope ^{137}Cs receives an accidental 100 mrem exposure. ^{137}Cs emits 0.66 MeV gamma-ray photons. How many gamma-ray photons are absorbed in the technician's body?

MODEL The radiation dose is a combination of deposited energy and biological effectiveness. The RBE for gamma rays is 1. Gamma rays are penetrating, so this is a whole-body exposure.

SOLVE The absorbed dose is the dose in Sv divided by the RBE. In this case, because RBE $= 1$ and 100 mrem $= 0.0010$ Sv, the dose is 0.0010 Gy $= 0.0010$ J/kg. This is a whole-body exposure, so the total energy deposited in the technician's body is 0.075 J. The energy of each absorbed photon is 0.66 MeV, but this value must be converted into joules. The number of photons in 0.075 J is

$$N = \frac{0.075\ \text{J}}{(6.6 \times 10^5\ \text{eV/photon})(1.60 \times 10^{-19}\ \text{J/eV})}$$
$$= 7.1 \times 10^{11}\ \text{photons}$$

ASSESS The energy deposited, 0.075 J, is very small. Radiation does its damage not by thermal effects, which would require substantially more energy, but by ionization.

Table 43.5 gives some basic information about radiation exposure. We are all exposed to a continuous natural background of radiation from cosmic rays and from naturally occurring radioactive atoms (uranium and other atoms in the uranium decay series) in the ground, the atmosphere, and even the food we eat. This background averages about 300 mrem per year, although there are wide regional variations depending on the soil type and the elevation. (Higher elevations have a larger exposure to cosmic rays.)

Medical x rays vary significantly. The average person in the United States receives approximately 60 mrem per year from all medical sources. All other sources, such as fallout from atmospheric nuclear tests many decades ago, nuclear power plants, and industrial uses of radioactivity, amount to <10 mrem per year.

The question inevitably arises: What is a safe dose? This remains a controversial topic and the subject of ongoing research. The effects of large doses of radiation are easily observed. The effects of small doses are hard to distinguish from other natural and environmental causes. Thus there's no simple or clear definition of a safe dose. A prudent policy is to avoid unnecessary exposure to radiation but not to worry over exposures less than the natural background. It's worth noting that the μCi radioactive sources used in laboratory experiments provide exposures *much* less than the natural background, even if used on a regular basis.

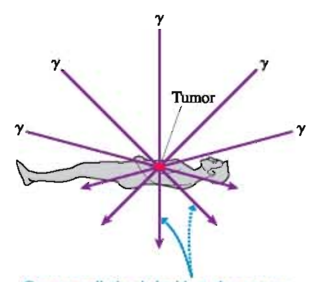
TABLE 43.5 Radiation exposure

Radiation source	Typical exposure (mrem)
CT scan	1000
Natural background (1 year)	300
Mammogram x ray	80
Chest x ray	30
Dental x ray	3

Medical Uses of Radiation

Radiation can be put to good use killing cancer cells. This area of medicine is called *radiation therapy*. Gamma rays are the most common form of radiation, often from the isotope ^{60}Co. As FIGURE 43.25 shows, the gamma rays are directed along many different lines, all of which intersect the tumor. The goal is to provide a lethal dose to the cancer cells without overexposing nearby tissue. The patient and the radiation source are rotated around each other under careful computer control to deliver the proper dose.

FIGURE 43.25 Radiation therapy is designed to deliver a lethal dose to the tumor without damaging nearby tissue.



Other tumors are treated by surgically implanting radioactive "seeds" within or next to the tumor. Alpha particles, which are very damaging locally but don't penetrate far, can be used in this fashion.

Radioactive isotopes are also used as *tracers* in diagnostic procedures. This technique is based on the fact that all isotopes of an element have identical chemical behavior. As an example, a radioactive isotope of iodine is used in the diagnosis of certain thyroid conditions. Iodine is an essential element in the body, and it concentrates in the thyroid gland. A doctor who suspects a malfunctioning thyroid gland gives the patient a small dose of sodium iodide in which some of the normal ^{127}I atoms have been replaced with ^{131}I. (Sodium iodide, which is harmless, dissolves in water and can simply be drunk.) The ^{131}I isotope, with a half-life of eight days, undergoes beta decay and subsequently emits a gamma-ray photon that can be detected.

Radiation therapy is a beneficial use of nuclear physics.

The radioactive iodine concentrates inside the thyroid gland within a few hours. The doctor then monitors the gamma-ray photon emissions over the next few days to see how the iodine is being processed within the thyroid and how quickly it is eliminated from the body.

Other important radioactive tracers include the chromium isotope ^{51}Cr, which is taken up by red blood cells and can be used to monitor blood flow, and the xenon isotope ^{133}Xe, which is inhaled to reveal lung functioning. Radioactive tracers are *noninvasive,* meaning that the doctor can monitor the inside of the body without surgery.

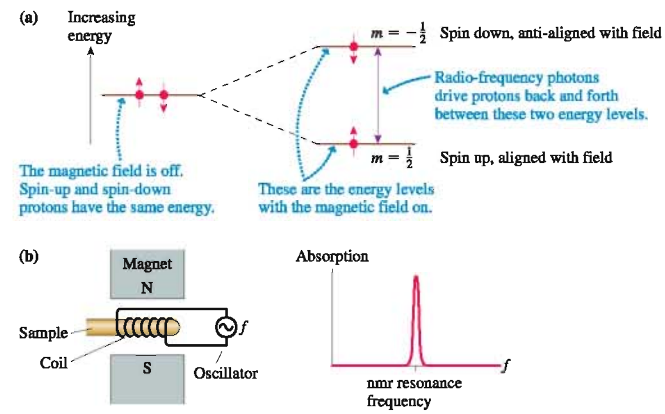
Magnetic Resonance Imaging

The proton, like the electron, has an inherent angular momentum (spin) and an inherent magnetic moment. You can think of the proton as being like a little compass needle that can be in one of two positions, the positions we call spin up and spin down.

A compass needle aligns itself with an external magnetic field. This is the needle's lowest-energy position. Turning a compass needle by hand is like rolling a ball uphill; you're giving it energy, but, like the ball rolling downhill, it will realign itself with the lowest-energy position when you remove your finger. There is, however, an *unstable equilibrium* position, like a ball at the top of a hill, in which the needle is anti-aligned with the field. The slightest jostle will cause it to flip around, but the needle will be steady in its upside-down configuration if you can balance it perfectly.

A proton in a magnetic field behaves similarly, but with a major difference: Because the proton's energy is quantized, the proton cannot assume an intermediate position. It's either aligned with the magnetic field (the spin-up orientation) or anti-aligned (spin-down). FIGURE 43.26a shows these two quantum states. Turning on a magnetic field lowers the energy of a spin-up proton and increases the energy of an anti-aligned, spin-down proton. In other words, the magnetic field creates an *energy difference* between these states.

FIGURE 43.26 Nuclear magnetic resonance is possible because spin-up and spin-down protons have slightly different energies in a magnetic field.



The energy difference is very tiny, only about 10^{-7} eV. Nonetheless, photons whose energy matches the energy difference cause the protons to move back and forth between these two energy levels as the photons are absorbed and emitted. In effect, the photons are causing the proton's spin to flip back and forth rapidly. The photon frequency, which depends on the magnetic field strength, is typically about 100 MHz, similar to FM radio frequencies.

FIGURE 43.26b shows how this behavior is put to use. A sample containing protons is placed in a magnetic field. A coil is wrapped around the sample, and a variable-frequency AC source drives a current through this coil. The protons absorb power from the coil when its frequency is just right to flip the spin back and forth; otherwise, no power is absorbed. A *resonance* is seen by scanning the coil through a small range of frequencies.

This technique of observing the spin flip of nuclei (the technique also works for nuclei other than hydrogen) in a magnetic field is called **nuclear magnetic resonance,** or *nmr*. It has many applications in physics, chemistry, and materials science. Its medical use exploits the fact that tissue is mostly water, and two out of the three nuclei in a water molecule are protons. Thus the human body is basically a sample of protons, with the proton density varying as the tissue density varies.

The medical procedure known as **magnetic resonance imaging,** or MRI, places the patient in a spatially varying magnetic field. The variations in the field cause the proton absorption frequency to vary from point to point. From the known shape of the field and measurements of the frequencies that are absorbed, and how strongly, sophisticated computer software can transform the raw data into detailed images such as the one shown in FIGURE 43.27.

As an interesting footnote, the technique was still being called *nuclear magnetic resonance* when it was first introduced into medicine. Unfortunately, doctors soon found that many patients were afraid of it because of the word "nuclear." Hence the alternative term "magnetic resonance imaging" was coined. It is true that the public perception of nuclear technology is not always positive, but equally true that nuclear physics has made many important and beneficial contributions to society.

FIGURE 43.27 Magnetic resonance imaging shows internal organs in exquisite detail.

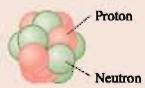
SUMMARY

The goal of Chapter 43 has been to understand the physics of the nucleus and some of the applications of nuclear physics.

General Principles

The Nucleus

The nucleus is a small, dense, positive core at the center of an atom.



Z protons: charge $+e$, spin $\frac{1}{2}$

N neutrons: charge 0, spin $\frac{1}{2}$

The **mass number** is $A = Z + N$.

The nuclear radius is $r = r_0 A^{1/3}$, where $r_0 = 1.2$ fm. Typical radii are a few fm.

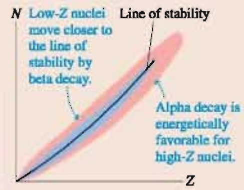
Nuclear forces

Attractive strong force
- Acts between any two nucleons
- Is short range, < 3 fm
- Is felt between nearest neighbors

Repulsive electric force
- Acts between two protons
- Is long range
- Is felt across the nucleus

Nuclear Stability

Most nuclei are not **stable**. Unstable nuclei undergo **radioactive decay**. Stable nuclei cluster along the **line of stability** in a plot of the isotopes.



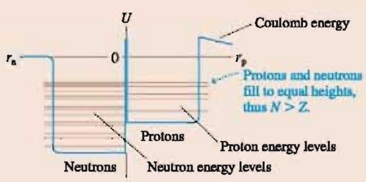
Three mechanisms by which unstable nuclei decay:

Decay	Particle	Mechanism	Energy	Penetration
α	^{4}He nucleus	tunneling	few MeV	low
β	e^-	$n \rightarrow p^+ + e^-$	≈ 1 MeV	medium
	e^+	$p^+ \rightarrow n + e^+$	≈ 1 MeV	medium
γ	photon	quantum jump	≈ 1 MeV	high

Important Concepts

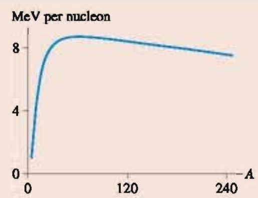
Shell model

Each nucleon moves with an average potential energy due to all other nucleons.



Curve of binding energy

The average binding energy per nucleon has a broad maximum at $A \approx 60$.



Applications

Radioactive decay

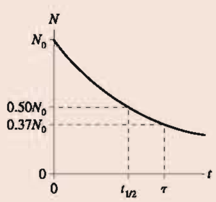
The number of undecayed nuclei decreases exponentially with time t:

$$N = N_0 \exp(-t/\tau)$$
$$= N_0 (1/2)^{t/t_{1/2}}$$

The **time constant** τ is $1/r$, where r is the **decay rate.** The **half-life**

$$t_{1/2} = \tau \ln 2 = 0.693\tau$$

is the time in which half of any sample decays.



Measuring radiation

The **activity** $R = rN$ of a radioactive sample, measured in becquerels or curies, is the number of decays per second.

The **absorbed dose** is measured in gray, where

$$1 \text{ Gy} \equiv 1.00 \text{ J/kg of absorbed energy}$$

The **relative biological effectiveness** (RBE) is the biological effect of a dose relative to the biological effects of x rays. The **dose equivalent** is measured in Sv, where Sv = Gy $\times$ RBE. One Sv of radiation produces the same biological effect regardless of the type of radiation. Dose equivalent is also measured in rem, where 1 rem = 0.010 Sv.

Terms and Notation

nuclear physics	liquid-drop model	decay rate, r	decay series

Problems labeled integrate significant material from earlier chapters.

CONCEPTUAL QUESTIONS

1. Consider the atoms ^{16}O, ^{18}O, ^{18}F, ^{18}Ne, and ^{20}Ne. Some of the following questions may have more than one answer. Give all answers that apply.
   a. Which are isotopes?
   b. Which are isobars?
   c. Which have the same chemical properties?
   d. Which have the same number of neutrons?
2. a. Is the binding energy of a nucleus with $A = 200$ more than, less than, or equal to the binding energy of a nucleus with $A = 60$? Explain.
   b. Is a nucleus with $A = 200$ more tightly bound, less tightly bound, or bound equally tightly as a nucleus with $A = 60$? Explain.
3. a. How do we know the strong force exists?
   b. How do we know the strong force is short range?
4. Does each nuclear energy-level diagram in FIGURE Q43.4 represent a nuclear ground state, an excited nuclear state, or an impossible nucleus? Explain.

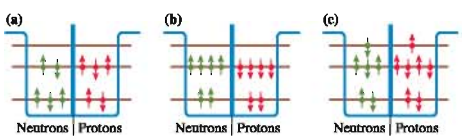

FIGURE Q43.4

5. Are the following decays possible? If not, why not?
   a. $^{232}Th\,(Z = 90) \rightarrow {}^{236}U\,(Z = 92) + \alpha$
   b. $^{238}Pu\,(Z = 94) \rightarrow {}^{236}U\,(Z = 92) + \alpha$
   c. $^{11}B\,(Z = 5) \rightarrow {}^{11}B\,(Z = 5) + \gamma$
   d. $^{33}P\,(Z = 15) \rightarrow {}^{32}S\,(Z = 16) + e^-$
6. Nucleus A decays into nucleus B with a half-life of 10 s. At $t = 0$ s, there are 1000 A nuclei and no B nuclei. At what time will there be 750 B nuclei?
7. What kind of decay, if any, can occur for the nuclei in FIGURE Q43.7?

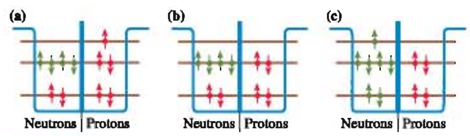

FIGURE Q43.7

8. Apple A in FIGURE Q43.8 is strongly irradiated by nuclear radiation for 1 hour. Apple B is not irradiated. Afterward, in what ways are apples A and B different?

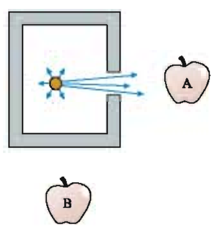

FIGURE Q43.8

9. The three isotopes ^{212}Po, ^{137}Cs, and ^{90}Sr decay as $^{212}Po \rightarrow {}^{208}Pb + \alpha$, $^{137}Cs \rightarrow {}^{127}Ba + e^- + \gamma$, and $^{90}Sr \rightarrow {}^{90}Y + e^-$. Which of these isotopes would be most useful as a biological tracer? Why?

EXERCISES AND PROBLEMS

See Appendix C for data on atomic masses, isotopic abundance, radioactive decay modes, and half-lives.

Exercises

Section 43.1 Nuclear Structure

1. | How many protons and how many neutrons are in (a) ^{3}H, (b) ^{40}Ar, (c) ^{40}Ca, and (d) ^{239}Pu?
2. | How many protons and how many neutrons are in (a) ^{6}Li, (b) ^{54}Cr, (c) ^{54}Fe, and (d) ^{220}Rn?
3. | Calculate the nuclear diameters of (a) ^{4}He, (b) ^{40}Ar, and (c) ^{220}Rn.
4. | Which stable nuclei have a diameter of 7.46 fm?
5. | Calculate the mass, radius, and density of the nucleus of (a) ^{7}Li and (b) ^{207}Pb. Give all answers in SI units.
6. || Estimate the number of protons and the number of neutrons in 1 m^3 of air.
7. || What would be the mass of a 1.0-cm-diameter marble if it had nuclear density?

Section 43.2 Nuclear Stability

8. | Use data in Appendix C to make your own chart of stable and unstable nuclei, similar to Figure 43.4, for all nuclei with $Z \leq 8$. Use a blue or black dot to represent stable isotopes, a red dot to represent isotopes that undergo beta-minus decay, and a green dot to represent isotopes that undergo beta-plus decay or electron-capture decay.
9. | a. What is the smallest value of A for which there are two stable nuclei? What are they?
   b. For which values of A less than this are there *no* stable nuclei?
10. | Calculate (in MeV) the total binding energy and the binding energy per nucleon for ^{3}H and for ^{3}He.
11. | Calculate (in MeV) the total binding energy and the binding energy per nucleon for ^{58}Fe and for ^{58}Ni.
12. | Calculate (in MeV) the binding energy per nucleon for ^{3}He and ^{4}He. Which is more tightly bound?
13. || Calculate (in MeV) the binding energy per nucleon for ^{12}C and ^{13}C. Which is more tightly bound?
14. || Calculate (in MeV) the binding energy per nucleon for (a) ^{12}C (b) ^{60}Co, and (c) ^{226}Ra.
15. | Calculate the chemical atomic mass of neon.
16. | Calculate the chemical atomic mass of magnesium.

Section 43.3 The Strong Force

17. || Use the potential-energy diagram in Figure 43.8 to estimate the strength of the strong force between two nucleons separated by 1.5 fm.
18. || Use the potential-energy diagram in Figure 43.8 to sketch an approximate graph of the strong force between two nucleons versus the distance r between their centers.
19. || What is the ratio of the gravitational potential energy to the nuclear potential energy for two neutrons separated by 1.0 fm?

Section 43.4 The Shell Model

20. | a. Draw energy-level diagrams, similar to Figure 43.11, for all $A = 10$ nuclei listed in Appendix C. Show all the occupied neutron and proton levels.
    b. Which of these nuclei are stable? What is the decay mode of any that are radioactive?
21. | a. Draw energy-level diagrams, similar to Figure 43.11, for all $A = 14$ nuclei listed in Appendix C. Show all the occupied neutron and proton levels.
    b. Which of these nuclei are stable? What is the decay mode of any that are radioactive?

Section 43.5 Radiation and Radioactivity

22. | The radium isotope ^{226}Ra has a half-life of 1600 years. A sample begins with 1.00×10^{10} ^{226}Ra atoms. How many are left after (a) 200 years, (b) 2000 years, and (c) 20,000 years?
23. | The cadmium isotope ^{109}Cd has a half-life of 462 days. A sample begins with 1.00×10^{12} ^{109}Cd atoms. How many are left after (a) 50 days, (b) 500 days, and (c) 5000 days?
24. || The radioactive hydrogen isotope ^{3}H is called *tritium*.
    a. What are the decay mode and the daughter nucleus of tritium?
    b. What are the time constant and the decay rate of tritium?
25. | A sample of 1.0×10^{10} atoms that decay by alpha emission has a half-life of 100 min. How many alpha particles are emitted between $t = 50$ min and $t = 200$ min?
26. | The activity of a ^{60}Co sample is 3.50×10^9 Bq. What is the mass of the sample?
27. || What is the half-life in days of a radioactive sample with 5.0×10^{15} atoms and an activity of 5.0×10^8 Bq?

Section 43.6 Nuclear Decay Mechanisms

28. | Identify the unknown isotope X in the following decays.
    a. $^{230}\mathrm{Th} \rightarrow \mathrm{X} + \alpha$
    b. $^{35}\mathrm{S} \rightarrow \mathrm{X} + e^- + \bar{\nu}$
    c. $\mathrm{X} \rightarrow {}^{40}\mathrm{K} + e^+ + \nu$
    d. $^{24}\mathrm{Na} \rightarrow {}^{24}\mathrm{Mg} + e^- + \bar{\nu} \rightarrow \mathrm{X} + \gamma$
29. | Identify the unknown isotope X in the following decays.
    a. $\mathrm{X} \rightarrow {}^{224}\mathrm{Ra} + \alpha$
    b. $\mathrm{X} \rightarrow {}^{207}\mathrm{Pb} + e^- + \bar{\nu}$
    c. $^7\mathrm{Be} + e^- \rightarrow \mathrm{X} + \nu$
    d. $\mathrm{X} \rightarrow {}^{60}\mathrm{Ni} + \gamma$
30. || What is the energy (in MeV) released in the alpha decay of ^{239}Pu?
31. || An unstable nucleus undergoes alpha decay with the release of 5.52 MeV of energy. The combined mass of the parent and daughter nuclei is 452 u. What was the parent nucleus?
32. || What is the total energy (in MeV) released in the beta-minus decay of ^{3}H?
    Hint: The daughter $^A\mathrm{Y}_{Z-1}$ is a positive ion. Tabulated masses are for neutral atoms.
33. || What is the total energy (in MeV) released in the beta-minus decay of ^{19}O? See the hint for Problem 32.
34. || What is the total energy (in MeV) released in the beta decay of a neutron?

Section 43.7 Biological Applications of Nuclear Physics

35. | 1.5 Gy of gamma radiation are directed into a 150 g tumor during radiation therapy. How much energy does the tumor absorb?

36. | The doctors planning a radiation therapy treatment have determined that a 100 g tumor needs to receive 0.20 J of gamma radiation. What is the dose in gray?

37. || A 50 kg laboratory worker is exposed to 20 mJ of beta radiation with RBE = 1.5. What is the dose in mrem?

38. || How many gray of gamma-ray photons cause the same biological damage as 30 Gy of alpha radiation with an RBE of 15?

Problems

39. ||| a. What initial speed must an alpha particle have to just touch the surface of a ^{197}Au gold nucleus before being turned back? Assume the nucleus stays at rest.
   b. What is the initial energy (in MeV) of the alpha particle?
   Hint: The alpha particle is not a point particle.

40. ||| Particle accelerators fire protons at target nuclei for investigators to study the nuclear reactions that occur. In one experiment, the proton needs to have 20 MeV of kinetic energy as it impacts a ^{207}Pb nucleus. With what initial kinetic energy (in MeV) must the proton be fired toward the lead target? Assume the nucleus stays at rest.
   Hint: The proton is not a point particle.

41. || Stars are powered by nuclear reactions that fuse hydrogen into helium. The fate of many stars, once most of the hydrogen is used up, is to collapse, under gravitational pull, into a *neutron star.* The force of gravity becomes so large that protons and electrons are fused into neutrons in the reaction $p^+ + e^- \rightarrow n + \nu$. The entire star is then a tightly packed ball of neutrons with the density of nuclear matter.
   a. Suppose the sun collapses into a neutron star. What will its radius be? Give your answer in km.
   b. The sun's rotation period is now 27 days. What will its rotation period be after it collapses?
   Rapidly rotating neutron stars emit pulses of radio waves at the rotation frequency and are known as *pulsars.*

42. || The element gallium has two stable isotopes: ^{69}Ga with an atomic mass of 68.92 u and ^{71}Ga with an atomic mass of 70.92 u. A periodic table shows that the chemical atomic mass of gallium is 69.72 u. What is the percent abundance of ^{69}Ga?

43. || You learned in Chapter 42 that the binding energy of the electron in a hydrogen atom is 13.6 eV.
   a. By how much does the mass decrease when a hydrogen atom is formed from a proton and an electron? Give your answer both in atomic mass units and as a percentage of the mass of the hydrogen atom.
   b. By how much does the mass decrease when a helium nucleus is formed from two protons and two neutrons? Give your answer both in atomic mass units and as a percentage of the mass of the helium nucleus.
   c. Compare your answers to parts a and b. Why do you hear it said that mass is "lost" in nuclear reactions but not in chemical reactions?

44. ||| Use the graph of binding energy to estimate the total energy released if a nucleus with mass number 240 fissions into two nuclei with mass number 120.

45. ||| Use the graph of binding energy to estimate the total energy released if three ^{4}He nuclei fuse together to form a ^{12}C nucleus.

46. || Could a ^{56}Fe nucleus fission into two ^{28}Al nuclei? Your answer, which should include some calculations, should be based on the curve of binding energy.

47. | a. What are the isotopic symbols of all $A = 17$ isobars?
   b. Which of these are stable nuclei?
   c. For those that are not stable, identify both the decay mode and the daughter nucleus.

48. | a. What are the isotopic symbols of all $A = 19$ isobars?
   b. Which of these are stable nuclei?
   c. For those that are not stable, identify both the decay mode and the daughter nucleus.

49. || Derive Equation 43.19 from Equation 43.15.

50. ||| What energy (in MeV) alpha particle has a de Broglie wavelength equal to the diameter of a ^{238}U nucleus?

51. || What is the activity in Bq and in Ci of a 2.0 mg sample of ^{3}H?

52. || What is the age in years of a bone in which the ^{14}C/^{12}C ratio is measured to be 1.65×10^{-13}?

53. || The activity of a sample of the cesium isotope ^{137}Cs, with a half-life of 30 years, is 2.0×10^8 Bq. Many years later, after the sample has fully decayed, how many beta particles will have been emitted?

54. || A 115 mCi radioactive tracer is made in a nuclear reactor. When it is delivered to a hospital 16 hours later its activity is 95 mCi. The lowest usable level of activity is 10 mCi.
   a. What is the tracer's half-life?
   b. For how long after delivery is the sample usable?

55. || The radium isotope ^{223}Ra, an alpha emitter, has a half-life of 11.43 days. You happen to have a 1.0 g cube of ^{223}Ra, so you decide to use it to boil water for tea. You fill a well-insulated container with 100 mL of water at 18° C and drop in the cube of radium.
   a. How long will it take the water to boil?
   b. Will the water have been altered in any way by this method of boiling? If so, how?

56. || How many half-lives must elapse until (a) 90% and (b) 99% of a radioactive sample of atoms has decayed?

57. || A sample contains radioactive atoms of two types, A and B. Initially there are five times as many A atoms as there are B atoms. Two hours later, the numbers of the two atoms are equal. The half-life of A is 0.50 hour. What is the half-life of B?

58. || Radioactive isotopes often occur together in mixtures. Suppose a 100 g sample contains ^{131}Ba, with a half-life of 12 days, and ^{47}Ca, with a half-life of 4.5 days. If there are initially twice as many calcium atoms as there are barium atoms, what will be the ratio of calcium atoms to barium atoms 2.5 weeks later?

59. || The technique known as potassium-argon dating is used to date old lava flows. The potassium isotope ^{40}K has a 1.28 billion year half-life and is naturally present at very low levels. ^{40}K decays by beta emission into ^{40}Ar. Argon is a gas, and there is no argon in flowing lava because the gas escapes. Once the lava solidifies, any argon produced in the decay of ^{40}K is trapped inside and cannot escape. A geologist brings you a piece of solidified lava in which you find the ^{40}Ar/^{40}K ratio to be 0.12. What is the age of the rock?

60. ‖ The half-life of the uranium isotope ^{235}U is 700 million years. The earth is approximately 4.5 billion years old. How much more ^{235}U was there when the earth formed than there is today? Give your answer as the then-to-now ratio.

61. ‖ A 75 kg patient swallows a 30 μCi beta emitter that is to be used as a tracer. The isotope's half-life is 5.0 days. The average energy of the beta particles is 0.35 MeV with an RBE of 1.5. Ninety percent of the beta particles are absorbed within the patient's body and 10% escape. What total dose (in mrem) does the patient receive?

62. ‖ What dose in gray of gamma radiation must be absorbed by a block of ice at 0°C to transform the entire block to liquid water at 0°C?

63. ‖ A chest x ray uses 10 keV photons with an RBE of 0.85. A 60 kg person receives a 0.30 mSv dose from one chest x ray that exposes 25% of the patient's body. How many x ray photons are absorbed in the patient's body?

64. ‖ The rate at which a radioactive tracer is lost from a patient's body is the rate at which the isotope decays *plus* the rate at which the element is excreted from the body. Medical experiments have shown that stable isotopes of a particular element are excreted with a 6.0 day half-life. A radioactive isotope of the same element has a half-life of 9.0 days. What is the effective half-life of the isotope in a patient's body?

65. ‖ The plutonium isotope ^{239}Pu has a half-life of 24,000 years and decays by the emission of a 5.2 MeV alpha particle. Plutonium is not especially dangerous if handled because the activity is low and the alpha radiation doesn't penetrate the skin. However, there are serious health concerns if even the tiniest particles of plutonium are inhaled and lodge deep in the lungs. This could happen following any kind of fire or explosion that disperses plutonium as dust. Let's determine the level of danger.
   a. Soot particles are roughly 1 μm in diameter, and it is known that these particles can go deep into the lungs. How many atoms are in a 1.0-μm-diameter particle of ^{239}Pu? The density of plutonium is 19,800 kg/m^3.
   b. What is the activity, in Bq, of a 1.0-μm-diameter particle?
   c. The activity of the particle is very small, but the penetrating power of alpha particles is also very small. The alpha particles are all stopped, and each deposits its energy in a 50-μm-diameter sphere around the particle. What is the dose, in rem/year, to this small sphere of tissue in the lungs? Use an average RBE of 15 and assume that the tissue density is that of water.
   d. Is this exposure likely to be significant? How does it compare to the natural background of radiation exposure?

Challenge Problems

66. The uranium isotope ^{238}U is naturally present at low levels in many soils. One of the nuclei in the decay series of ^{238}U is the radon isotope ^{222}Rn, which decays by emitting a 5.50 MeV alpha particle with $t_{1/2} = 3.82$ days. Radon is a gas, and it tends to seep from soil into basements. The Environmental Protection Agency recommends that homeowners take steps to remove radon, by pumping in fresh air, if the radon activity exceeds 4 pCi per liter of air.
   a. How many ^{222}Rn atoms are there in 1 m^3 of air if the activity is 4 pCi/L?
   b. The range of alpha particles in air is ≈3 cm. Suppose we model a person as a 180-cm-tall, 25-cm-diameter cylinder with a mass of 65 kg. Only decays within 3 cm of the cylinder can cause exposure, and only ≈50% of the decays direct the alpha particle toward the person. Determine the dose in mrem per year for a person who spends the entire year in a room where the activity is 4 pCi/L. Assume an average RBE of 15.
   c. Does the EPA recommendation seem appropriate? Why or why not?

67. Estimate the stopping distance in air of a 5.0 MeV alpha particle. Assume that the particle loses on average 30 eV per collision.

68. Beta-plus decay is $^A X_Z \rightarrow {}^A Y_{Z-1} + e^+ + \nu$.
   a. Determine the mass threshold for beta-plus decay. That is, what is the minimum atomic mass m_X for which this decay is energetically possible? Your answer will be in terms of the atomic mass m_Y and the electron mass m_e.
   Hint: Start with the nuclear masses, then add an equal number of electrons to both sides of the reaction to get atomic masses.
   b. Can ^{13}N undergo beta-plus decay into ^{13}C? If so, how much energy is released in the decay?

69. All the very heavy atoms found in the earth were created long ago by nuclear fusion reactions in a supernova, an exploding star. The debris spewed out by the supernova later coalesced into the gases from which the sun and the planets of our solar system were formed. Nuclear physics suggests that the uranium isotopes ^{235}U and ^{238}U should have been created in roughly equal numbers. Today, 99.28% of uranium is ^{238}U and only 0.72% is ^{235}U. How long ago did the supernova occur?

70. It might seem strange that in beta decay the positive proton, which is repelled by the positive nucleus, remains in the nucleus while the negative electron, which is attracted to the nucleus, is ejected. To understand beta decay, let's analyze the decay of a free neutron that is at rest in the laboratory. We'll ignore the antineutrino and consider the decay $n \rightarrow p^+ + e^-$. The analysis requires the use of relativistic energy and momentum, from Chapter 37.
   a. What is the total kinetic energy, in MeV, of the proton and electron?
   b. Write the equation that expresses the conservation of relativistic energy for this decay. Your equation will be in terms of the three masses m_n, m_p, and m_e and the relativistic factors γ_p and γ_e.
   c. Write the equation that expresses the conservation of relativistic momentum for this decay. Let v represent speed, rather than velocity, then write any minus signs explicitly.
   d. You have two simultaneous equations in the two unknowns v_p and v_e. To help in solving these, first prove that $\gamma v = (\gamma^2 - 1)^{1/2} c$.
   e. Solve for v_p and v_e. (It's easiest to solve for γ_p and γ_e, then find v from γ.) First get an algebraic expression for each, in terms of the masses. Then evaluate each, giving v as a fraction of c.

f. Calculate the kinetic energy in MeV of the proton and the electron. Verify that their sum matches your answer to part a.
g. Now explain why the electron is ejected in beta decay while the proton remains in the nucleus.

71. Alpha decay occurs when an alpha particle tunnels through the Coulomb barrier. FIGURE CP42.71 shows a simple one-dimensional model of the potential-energy well of an alpha particle in a nucleus with $A \approx 235$. The 15 fm width of this one-dimensional potential-energy well is the *diameter* of the nucleus. Further, to keep the model simple, the Coulomb barrier has been modeled as a 20-fm-wide, 30-MeV-high rectangular potential-energy barrier. The goal of this problem is to calculate the half-life of an alpha particle in the energy level $E = 5.0$ MeV.

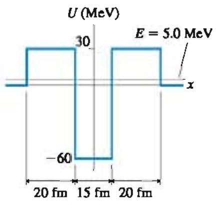

FIGURE CP43.71

a. What is the kinetic energy of the alpha particle while inside the nucleus? What is its kinetic energy after it escapes from the nucleus?
b. Consider the alpha particle within the nucleus to be a point particle bouncing back and forth with the kinetic energy you stated in part a. What is the particle's *collision rate,* the number of times per second it collides with a wall of the potential-energy barrier?
c. What is the tunneling probability P_{tunnel}?
d. P_{tunnel} is the probability that on any one collision with a wall the alpha particle tunnels through instead of reflecting. The probability of *not* tunneling is $1 - P_{tunnel}$. Hence the probability that the alpha particle is still inside the nucleus after N collisions is $(1 - P_{tunnel})^N \approx 1 - NP_{tunnel}$, where we've used the binomial approximation because $P_{tunnel} \ll 1$. The half-life is the *time* at which half the nuclei have not yet decayed. Use this information to determine (in years) the half-life of this nucleus.

STOP TO THINK ANSWERS

Stop to Think 43.1: 3. Different isotopes of an element have different numbers of neutrons but the same number of protons. The number of electrons in a neutral atom matches the number of protons.

Stop to Think 43.2: d. To keep A constant, increasing N by 1 requires decreasing Z by 1.

Stop to Think 43.3: No. A Geiger counter responds only to ionizing radiation. Visible light is not ionizing radiation.

Stop to Think 43.4: c. One-quarter of the atoms are left. This is one-half of one-half, or $(1/2)^2$.

Stop to Think 43.5: b. An increase of Z with no change in A occurs when a neutron changes to a proton and an electron, ejecting the electron.

PART

VII SUMMARY Relativity and Quantum Physics

Niels Bohr was right on target with his remark, "Anyone who is not shocked by quantum theory has not understood it." Quantum mechanics *is* shocking. The predictability of Newtonian physics has been replaced by a mysterious world in which physical entities that by all rights should be waves sometimes act like particles. Electrons and neutrons somehow produce wave-like interference with themselves. These discoveries stood common sense on its head.

According to quantum mechanics, the wave function and its associated probabilities are *all we can know* about an atomic particle. This idea is so unsettling that many great scientists were reluctant to accept it. Einstein famously said, "God does not play dice with the universe." But Einstein was wrong. As strange as it seems, this is the way that nature really is.

As we conclude our journey into physics, the knowledge structure for Part VII summarizes the important ideas of relativity and quantum physics. Whether you're shocked or not, these are the scientific theories behind the emerging technologies of the 21st century.

KNOWLEDGE STRUCTURE VII Relativity and Quantum Physics

ESSENTIAL CONCEPTS	Reference frame, event, atom, photon, quantization, wave function, probability density
BASIC GOALS	What are the properties and characteristics of space and time? How do we know about light and atoms? How are atomic and nuclear phenomena explained by energy levels, wave functions, and photons?

GENERAL PRINCIPLES	**Principle of relativity**	All the laws of physics are the same in all inertial reference frames.
	Schrödinger's equation	$\dfrac{d^2\psi}{dx^2} = -\dfrac{2m}{\hbar^2}[E - U(x)]\psi(x)$
	Pauli exclusion principle	No more than one electron or nucleon can occupy the same quantum state.
	Uncertainty principle	$\Delta x \Delta p \geq h/2$

RELATIVITY It follows from the principle of relativity that:

- The speed of light c is the same in all inertial reference frames. No particle or causal influence can travel faster than c.
- Length contraction: The length of an object in a reference frame in which the object moves with speed v is

$$L = \sqrt{1 - \beta^2}\,\ell \leq \ell$$

  where ℓ is the proper length and $\beta = v/c$.
- Time dilation: The proper time interval $\Delta\tau$ between two events is measured in a reference frame in which the two events occur at the same position. The time interval Δt in a frame moving with relative speed v is

$$\Delta t = \Delta\tau/\sqrt{1 - \beta^2} \geq \Delta\tau$$

- $E = mc^2$ is the energy equivalent of mass. Mass can be transformed into energy and energy into mass.

QUANTUM PHYSICS Quantum systems are described by a wave function $\psi(x)$.

- The probability that a particle will be found in the narrow interval δx at position x is Prob(in δx at x) $= P(x)\,\delta x$. The probability density is $P(x) = |\psi(x)|^2$.
- The wave function must be normalized

$$\int_{-\infty}^{\infty} |\psi(x)|^2\,dx = 1$$

- The wave function can penetrate into a classically forbidden region with penetration distance

$$\eta = \frac{\hbar}{\sqrt{2m(U_0 - E)}}$$

- A particle can tunnel through an energy barrier of height U_0 and width w with probability $P_{tunnel} = e^{-2w/\eta}$

Properties of light

- A photon of light of frequency f has energy $E_{photon} = hf$.
- Photons are emitted and absorbed on an all-or-nothing basis.

Properties of atoms

- Quantized energy levels, found by solving the Schrödinger equation, depend on quantum numbers n and l.
- An atom can jump from one state to another by emitting or absorbing a photon of energy $E_{photon} = \Delta E_{atom}$.
- The ground-state electron configuration is the lowest-energy configuration consistent with the Pauli principle.

Properties of nuclei

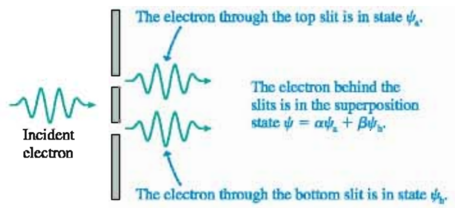
- The nucleus is held together by the strong force, an attractive short-range force between any two nucleons.
- Nuclei are stable only if the proton and neutron numbers fall along the line of stability.
- Unstable nuclei decay by alpha, beta, or gamma decay. The number of nuclei decreases exponentially with time.

Quantum Computers

All the systems we studied in Part VII were in a single, well-defined quantum state. For example, a hydrogen atom was in the $1s$ state or, perhaps, the $2p$ state. But there's another possibility. Some quantum systems can exist in a *superposition* of two or more quantum states.

We hinted at the possibility of superposition when we reexamined the double-slit interference experiment in the light of quantum physics. We noted that a photon or electron must, in some sense, go through both slits and then interfere with itself to produce the dot-by-dot buildup of an interference pattern on the screen. Suppose we say that an electron that has passed through the top slit in the figure is in quantum state ψ_a. An electron that has passed through the bottom slit is in state ψ_b.

FIGURE PSVII.1 The electron emerging from the double slit is in a superposition state.



To say that the electron goes through both slits is to say that the electron emerges from the double slit in the *superposition state* $\psi = \alpha\psi_a + \beta\psi_b$, where the coefficients α and β must satisfy $\alpha^2 + \beta^2 = 1$. (Notice that this is like finding the magnitude of a vector from its components.) If we were to detect the electron, α^2 and β^2 are the probabilities that we would find it to be in state ψ_a or state ψ_b, respectively. But until we detect it, the electron exists in the superposition of *both* states ψ_a and ψ_b. It is this superposition that allows the electron to interfere with itself to produce the interference pattern.

But what does this have to do with computers? As you know, everything a modern digital computer does, from surfing the Internet to crunching numbers, is accomplished by manipulating binary strings of 0s and 1s. The *concept* of computing with binary bits goes back to Charles Babbage in the mid–19th century, but it wasn't until the mid–20th century that scientists and engineers developed the technology that gives this concept a physical representation.

A binary bit is always a 1 or a 0; there's no in-between state. These are represented in a modern microprocessor by small capacitors that are either charged or uncharged. Suppose we wanted to represent information not with capacitors but with a quantum system that has two states. We could say that the system represents a 0 when it is in state ψ_a and a 1 when it is in ψ_b. Such a quantum system is an ordinary binary bit as long as the system is in one state or the other.

But the quantum system, unlike a classical bit, has the possibility of being in a superposition state. Using 0 and 1, rather than ψ_a and ψ_b, we could say that the system can be in the state $\psi = \alpha \cdot 0 + \beta \cdot 1$. This basic unit of quantum computing is called a ***qubit***. It may seem at first that we could do the same thing with a classical system by allowing the capacitor charge to vary, but a partially charged capacitor is still a single, well-defined state. In contrast, the qubit—like the electron that goes through both slits—is simultaneously in both state 0 *and* state 1.

To illustrate the possibilities, suppose you have three classical bits and three qubits. The three bits can represent eight different numbers (000 to 111), but only one at a time. The three qubits represent all eight numbers *simultaneously*. To perform a mathematical operation, you must do it eight times on the three bits to learn all the possible outcomes. But you would learn all eight outcomes simultaneously from *one* operation on the three qubits. In general, computing with n qubits provides a theoretical improvement of 2^n over computing with n bits.

We say "theoretical" because quantum computing is still mostly in the concept stage, much as digital computers were 150 years ago. What kind of quantum systems can actually be placed in an appropriate superposition state? How do you manipulate qubits? How do you read information in and out? What kinds of computations would be improved by quantum computing?

These are all questions that are being actively researched today. Quantum computing is in its infancy, and the technology for making a real quantum computer is largely unknown. Just as Charles Babbage couldn't possibly have imagined today's computers, the uses of tomorrow's quantum computers are still unforeseen. But, quite possibly, there are uses that some of you may help to invent.

FIGURE PSVII.1 This string of beryllium ions held in an ion trap is being studied as a possible quantum computer. The quantum states of the ions are manipulated with laser beams.

Mathematics Review

Algebra

Using exponents: $a^{-x} = \dfrac{1}{a^x}$ $\qquad a^x a^y = a^{(x+y)}$ $\qquad \dfrac{a^x}{a^y} = a^{(x-y)}$ $\qquad (a^x)^y = a^{xy}$

$a^0 = 1$ $\qquad a^1 = a$ $\qquad a^{1/n} = \sqrt[n]{a}$

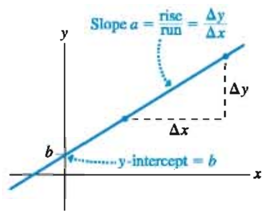
Fractions: $\left(\dfrac{a}{b}\right)\left(\dfrac{c}{d}\right) = \dfrac{ac}{bd}$ $\qquad \dfrac{a/b}{c/d} = \dfrac{ad}{bc}$ $\qquad \dfrac{1}{1/a} = a$

Logarithms: If $a = e^x$, then $\ln(a) = x$ $\qquad \ln(e^x) = x$ $\qquad e^{\ln(x)} = x$

$\ln(ab) = \ln(a) + \ln(b)$ $\qquad \ln\left(\dfrac{a}{b}\right) = \ln(a) - \ln(b)$ $\qquad \ln(a^n) = n\ln(a)$

The expression $\ln(a + b)$ cannot be simplified.

Linear equations: The graph of the equation $y = ax + b$ is a straight line. a is the slope of the graph. b is the y-intercept.



Proportionality: To say that y is proportional to x, written $y \propto x$, means that $y = ax$, where a is a constant. Proportionality is a special case of linearity. A graph of a proportional relationship is a straight line that passes through the origin. If $y \propto x$, then

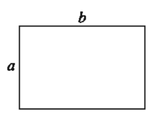
$$\frac{y_1}{y_2} = \frac{x_1}{x_2}$$

Quadratic equation: The quadratic equation $ax^2 + bx + c = 0$ has the two solutions $x = \dfrac{-b \pm \sqrt{b^2 - 4ac}}{2a}$.

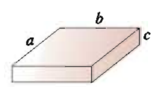
Geometry and Trigonometry

Area and volume:

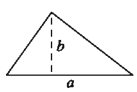
Rectangle
$A = ab$



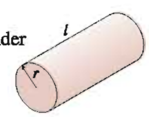
Rectangular box
$V = abc$



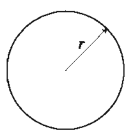
Triangle
$A = \frac{1}{2}ab$



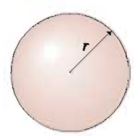
Right circular cylinder
$V = \pi r^2 l$



Circle
$C = 2\pi r$
$A = \pi r^2$



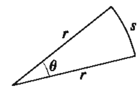
Sphere
$A = 4\pi r^2$
$V = \frac{4}{3}\pi r^3$



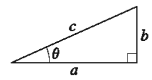
Arc length and angle: The angle θ in radians is defined as $\theta = s/r$.

The arc length that spans angle θ is $s = r\theta$.

$2\pi \text{ rad} = 360°$



Right triangle: Pythagorean theorem $c = \sqrt{a^2 + b^2}$ or $a^2 + b^2 = c^2$



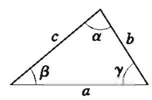
$$\sin\theta = \frac{b}{c} = \frac{\text{far side}}{\text{hypotenuse}} \qquad \theta = \sin^{-1}\left(\frac{b}{c}\right)$$

$$\cos\theta = \frac{a}{c} = \frac{\text{adjacent side}}{\text{hypotenuse}} \qquad \theta = \cos^{-1}\left(\frac{a}{c}\right)$$

$$\tan\theta = \frac{b}{a} = \frac{\text{far side}}{\text{adjacent side}} \qquad \theta = \tan^{-1}\left(\frac{b}{a}\right)$$

General triangle: $\alpha + \beta + \gamma = 180° = \pi \text{ rad}$

Law of cosines $c^2 = a^2 + b^2 - 2ab\cos\gamma$



Identities:

$\tan\alpha = \dfrac{\sin\alpha}{\cos\alpha}$	$\sin^2\alpha + \cos^2\alpha = 1$
$\sin(-\alpha) = -\sin\alpha$	$\cos(-\alpha) = \cos\alpha$
$\sin(\alpha \pm \beta) = \sin\alpha\cos\beta \pm \cos\alpha\sin\beta$	$\cos(\alpha \pm \beta) = \cos\alpha\cos\beta \mp \sin\alpha\sin\beta$
$\sin(2\alpha) = 2\sin\alpha\cos\alpha$	$\cos(2\alpha) = \cos^2\alpha - \sin^2\alpha$
$\sin(\alpha \pm \pi/2) = \pm\cos\alpha$	$\cos(\alpha \pm \pi/2) = \mp\sin\alpha$
$\sin(\alpha \pm \pi) = -\sin\alpha$	$\cos(\alpha \pm \pi) = -\cos\alpha$

Expansions and Approximations

Binomial expansion: $(1 + x)^n = 1 + nx + \dfrac{n(n-1)}{2}x^2 + \cdots$

Binomial approximation: $(1 + x)^n \approx 1 + nx \quad \text{if} \quad x \ll 1$

Trigonometric expansions:

$$\sin\alpha = \alpha - \frac{\alpha^3}{3!} + \frac{\alpha^5}{5!} - \frac{\alpha^7}{7!} + \cdots \quad \text{for } \alpha \text{ in rad}$$

$$\cos\alpha = 1 - \frac{\alpha^2}{2!} + \frac{\alpha^4}{4!} - \frac{\alpha^6}{6!} + \cdots \quad \text{for } \alpha \text{ in rad}$$

Small-angle approximation: If $\alpha \ll 1$ rad, then $\sin\alpha \approx \tan\alpha \approx \alpha$ and $\cos\alpha \approx 1$.

The small-angle approximation is excellent for $\alpha < 5°$ (≈ 0.1 rad) and generally acceptable up to $\alpha \approx 10°$.

Calculus

The letters *a* and *n* represent constants in the following derivatives and integrals.

Derivatives

$$\frac{d}{dx}(a) = 0$$

$$\frac{d}{dx}(ax) = a$$

$$\frac{d}{dx}\left(\frac{a}{x}\right) = -\frac{a}{x^2}$$

$$\frac{d}{dx}(ax^n) = anx^{n-1}$$

$$\frac{d}{dx}(\ln(ax)) = \frac{1}{x}$$

$$\frac{d}{dx}(e^{ax}) = ae^{ax}$$

$$\frac{d}{dx}(\sin(ax)) = a\cos(ax)$$

$$\frac{d}{dx}(\cos(ax)) = -a\sin(ax)$$

Integrals

$$\int x\,dx = \frac{1}{2}x^2$$

$$\int x^2\,dx = \frac{1}{3}x^3$$

$$\int \frac{1}{x^2}\,dx = -\frac{1}{x}$$

$$\int x^n\,dx = \frac{x^{n+1}}{n+1} \qquad n \neq -1$$

$$\int \frac{dx}{x} = \ln x$$

$$\int \frac{dx}{a+x} = \ln(a+x)$$

$$\int \frac{x\,dx}{a+x} = x - a\ln(a+x)$$

$$\int \frac{dx}{\sqrt{x^2 \pm a^2}} = \ln\left(x + \sqrt{x^2 \pm a^2}\right)$$

$$\int \frac{x\,dx}{\sqrt{x^2 \pm a^2}} = \sqrt{x^2 \pm a^2}$$

$$\int \frac{dx}{x^2 + a^2} = \frac{1}{a}\tan^{-1}\left(\frac{x}{a}\right)$$

$$\int \frac{dx}{(x^2 + a^2)^2} = \frac{1}{2a^3}\tan^{-1}\left(\frac{x}{a}\right) + \frac{x}{2a^2(x^2 + a^2)}$$

$$\int \frac{dx}{(x^2 \pm a^2)^{3/2}} = \frac{\pm x}{a^2\sqrt{x^2 \pm a^2}}$$

$$\int \frac{x\,dx}{(x^2 \pm a^2)^{3/2}} = -\frac{1}{\sqrt{x^2 \pm a^2}}$$

$$\int e^{ax}\,dx = \frac{1}{a}e^{ax}$$

$$\int xe^{ax}\,dx = \frac{1}{a^2}e^{ax}(ax - 1)$$

$$\int \sin(ax)\,dx = -\frac{1}{a}\cos(ax)$$

$$\int \cos(ax)\,dx = \frac{1}{a}\sin(ax)$$

$$\int \sin^2(ax)\,dx = \frac{x}{2} - \frac{\sin(2ax)}{4a}$$

$$\int \cos^2(ax)\,dx = \frac{x}{2} + \frac{\sin(2ax)}{4a}$$

$$\int_0^\infty x^n e^{-ax}\,dx = \frac{n!}{a^{n+1}}$$

$$\int_0^\infty e^{-ax^2}\,dx = \frac{1}{2}\sqrt{\frac{\pi}{a}}$$

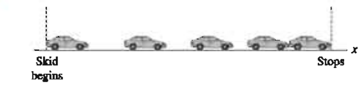
Answers

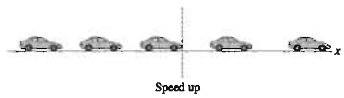
Answers to Odd-Numbered Exercises and Problems

Chapter 1

1.

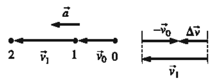


3.



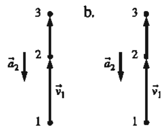
7.

9. a.

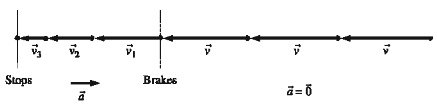


b. Greater

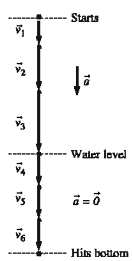
11. a. b.



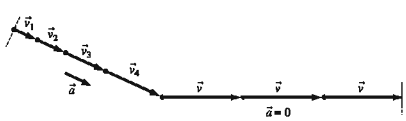
13.



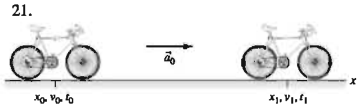
15.



17.



21.

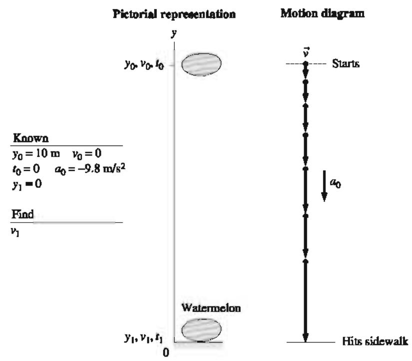


Known
$v_0 = 0 \quad t_0 = 0 \quad x_0 = 0$
$a_0 = 1.5\ \text{m/s}^2$
$v_1 = 7.5\ \text{m/s}$

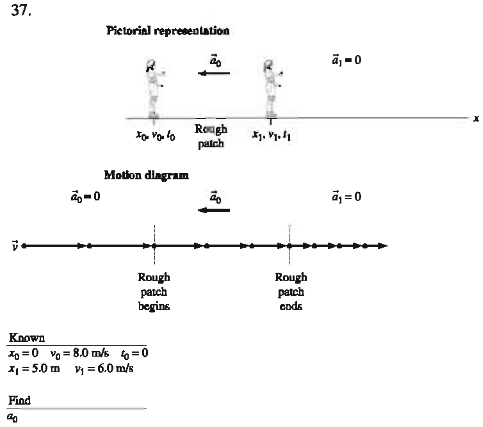
Find
x_1

23. a. 9.12×10^{-6} s b. 3.42×10^{3} m c. 4.4×10^{2} m/s d. 22 m/s
25. a. 3600 s b. 86,400 s c. 3.16×10^{7} s d. 9.75 m/s^2
27. a. 12 in b. 50 mph c. 3 mi d. 1/4 in
29. a. 1.109×10^{3} b. 1.50×10^{3} c. 3.5 d. 0.0225
31. 50 ft or 15 m, about 8 times my height
33. 9.8×10^{-9} m/s = 35 μm/h

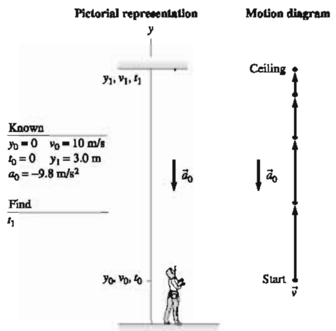
35.



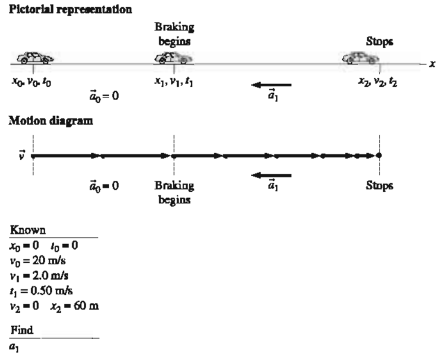
37.



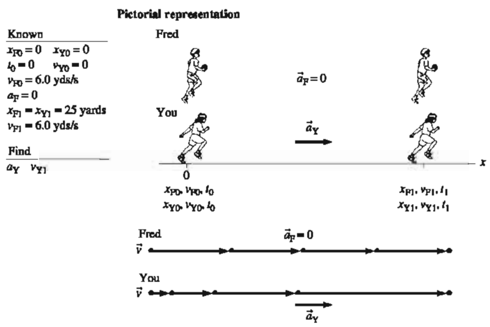
39.



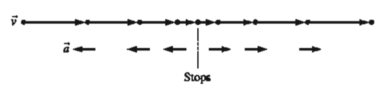
41.



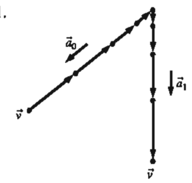
43.



49.

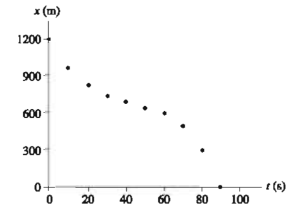


51.



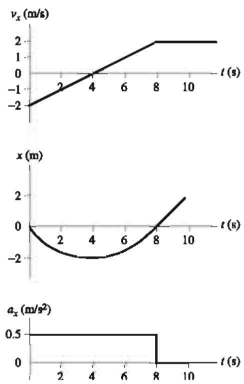
53. Smallest: 6.4×10^3 m², largest: 8.3×10^3 m²

55.



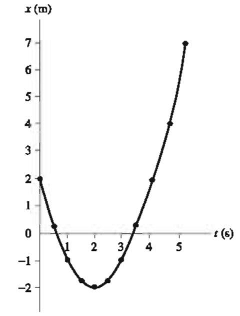
Chapter 2

1. 450 m
3. a. Beth b. 20 min
5. 2.5 m/s, 0 m/s, −10 m/s
7. a. At t = 1 s b. 10 m, 16 m, 26 m
9. a. 0.5 m/s²
   b.



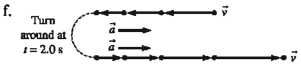
11. a. 6 m, 4 m/s, 0 m/s² b. 13.0 m, 2 m/s, −2 m/s
13. −2.8 m/s²
15. a. 78.4 m b. −39.2 m/s
17. 3.2 s
19. a. 64 m b. 7.1 s
21. a. 7 m b. 7 m/s c. 7 m/s²
23. 16 m/s

25. a.



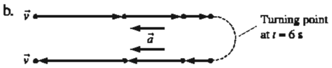
c. -2 m/s d. -2 m e. 2 m

f.



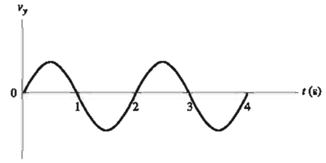
27. a. 4 s, 8 s

b.



29. a. Zero at $t = 0$ s, 1 s, 2 s, 3 s, . . . ; most positive at $t = 0.5$ s, 2.5 s, . . . ; most negative at $t = 1.5$ s, 3.5 s, . . .

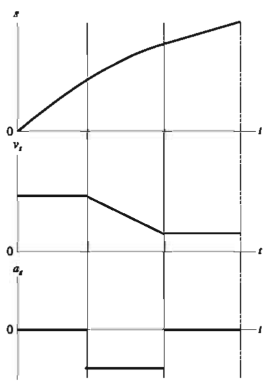
b.



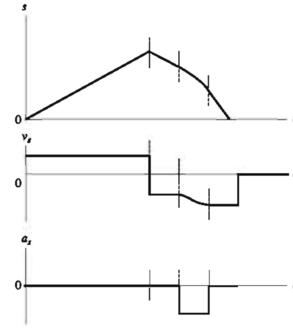
31. a. 0 s and 3 s b. 12 m and -18 m/s^2; -15 m and 18 m/s^2

33. 2.0 m/s^3

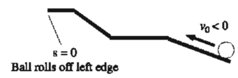
35.



37.



39.



41. a. 179 mph b. Yes c. 35 s d. No

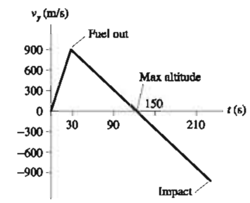
43. a. 2.7 m/s^2 b. 28% c. 1.3×10^2 m $= 4.3 \times 10^2$ ft

45. Yes

47. a. 5 m b. 22 m/s

49. a. 54.8 km b. 228 s

c.



51. 19.7 m

53. 216 m

55. 9.9 m/s

57. a. 2.32 m/s b. 5.00 m/s c. 0%

59. Yes

61. a. 214 km/h b. 16%

63. 14 m/s

65. a. 24 m/s, 35 m/s b. $\sqrt{\dfrac{P}{2mt}}$ c. 3.9 m/s^2, 1.2 m/s^2

d. $a_x \to \infty$ as $t \to 0$ e. $\dfrac{2}{3}\sqrt{\dfrac{2P}{m}}\,t^{3/2}$ f. 18.2 s

67. No

69. 17.2 m

71. 4.4 m/s^2

73. c. 17.2 m/s

75. c. $x_1 = 250$ m, $x_2 = 750$ m

77. 5.5 m/s^2

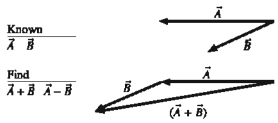
79. a. 10 s b. 3.8 m/s^2 c. 5.6%

81. 12.5 m/s^2

83. -4500 m/s^2

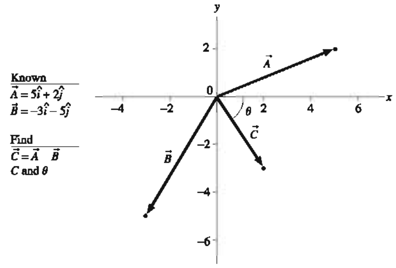
Chapter 3

1. a.

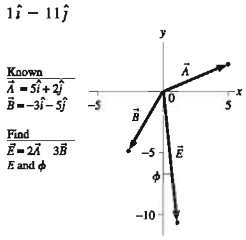


b.

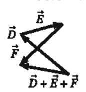
3. a. $-E\cos\theta, E\sin\theta$ b. $E_x = -E\sin\phi, E_y = E\cos\phi$
5. 12 m/s
7. a. -5 cm/s, 0 cm/s b. -6.4 m/s^2, -7.7 m/s^2 c. 30 N, 40 N
9. 280 V/m, 63.4° below the $+x$-axis
11. a. 7.21, 56.3° below the $+x$-axis
b. 94.3 m, 58.0° above the $+x$-axis
c. 44.7 m/s, 63.4° above the $-x$-axis
d. 6.3 m/s^2, 18.4° right of the $-y$-axis
13. a. $2\hat{\imath} - 3\hat{\jmath}$ c. 3.6, 56° below the $+x$-axis
b.



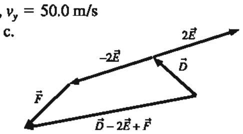
15. a. $1\hat{\imath} - 11\hat{\jmath}$
b.



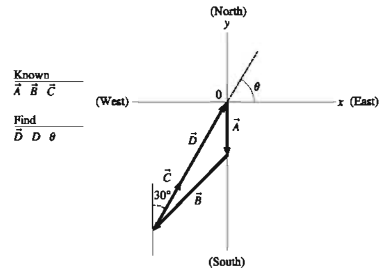
c. 11.05, 5.19° right of $-y$-axis
17. a. False b. False c. True
19. $v_x = -86.6$ m/s, $v_y = 50.0$ m/s
21. a.



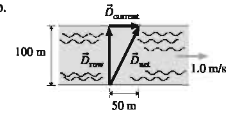
c.



23. a. 0 m, 25.6 m, 160 m b. $(10\hat{\imath} + 8\hat{\jmath})t$ m/s c. 0 m/s, 25.6 m/s, 64.0 m/s
25. a. $-6\hat{\imath} + 2\hat{\jmath}$ b. 6.3, 18° above the $-x$-axis
27. $-1.1\hat{\imath} - 3.0\hat{\jmath}$
29. $0.707\hat{\imath} + 0.707\hat{\jmath}$
31. a. 100 m lower b. 5.03 km
33. a.



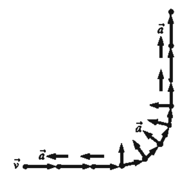
b. 360 m, 59.4° north of east
35. 7.5 m
37. a. 34° b. 1.7 m/s
39. a. 50 m b.



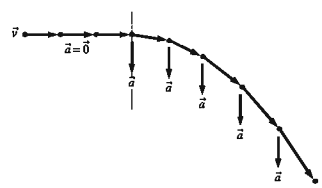
41. -15.0 m/s
43. a. 1.0 m/s^2 b. 1.7 m/s^2
45. i downhill $j \parallel F_2$ (with the x-axis downhill and the y-axis parallel to F_2). a. 0.50 N up the slope b. 1.67 N c. 1.74 N, 73° above the floor on the left side of F_2

Chapter 4

1. a.

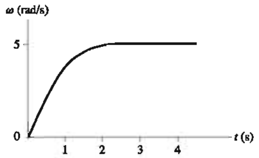


3. a.

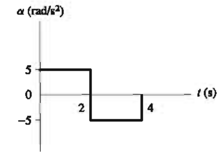


5. 9.21 m/s, 20° north of east
7. $(10.00\hat{\imath} - 15.00\hat{\jmath})$ m/s^2
9. a. 2.2 m/s^2 b. 0 m, 28 m, 50 m
11. 19.6 m
13. 678 m
15. $-(154\text{ m})\hat{\imath} + (354\text{ m})\hat{\jmath}$
17. 30 s
19. 75 mph
21. 9.55 revolutions
23. a. 1.5π rad/s b. 1.33 s
25. 2.18×10^{-2} m/s
27. 34 m/s
29. a. 5.7 m/s b. 108 m/s^2

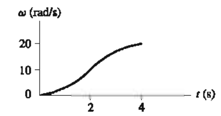
31.



33. a.

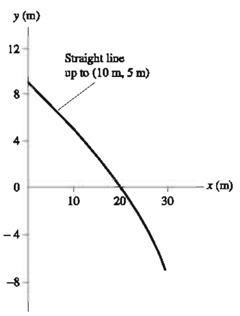


b.



35. a. 3.9 m/s b. 2.49 rev c. 15.6 rad
37. 47 rad/s^2
39. a. 3 s b. -8 m/s

c.

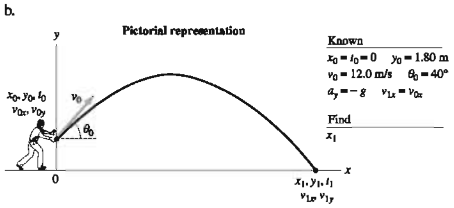


41. a. $v_0^2 \sin^2\theta/2g$

b. h = 14.4 m, 28.8 m, 43.2 m; d = 99.8 m, 115.2 m, 99.8 m

43. a. 16.36 m

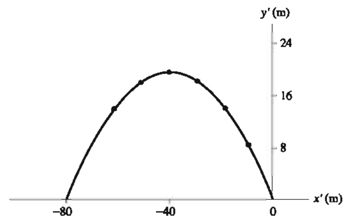
b.



Maximum distance is achieved at $\theta \approx 42.5°$.

45. a. 26 m b. 34 m c. 20 m/s
47. a. 28 m/s b. 22 m/s to 44 m/s
49. a. 13.3 m/s b. 48°
51. a. 2.4×10^2 m b. 43 m
53. 80 cm
55. a. 39 mi b. 19.5 mph
57. If Nancy drives in the x-direction of Mike's throw: a. 44.4° above the $-x'$-axis

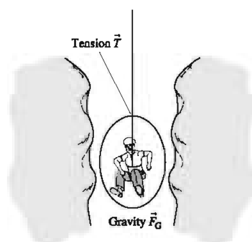
b.



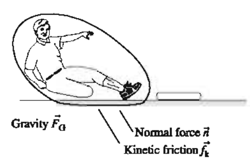
59. 69 m/s at 21° from the vertical
61. a. 1.75×10^4 m/s^2 b. 4.4×10^3 m/s^2
63. 50°
65. a. 3.07×10^3 m/s b. 0.223 m/s^2
67. a. -100 rad/s^2 b. 50 rev
69. 98 rpm
71. 50 revolutions
73. 5.5×10^2 rpm
75. b. $x_1 = -30$ m
79. 34.3°
81. 297 m
83. 3.8 m
85. $\frac{1}{2}\tan^{-1}\left(\frac{g}{a}\right)$
87. 65°

Chapter 5

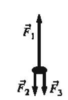
1.



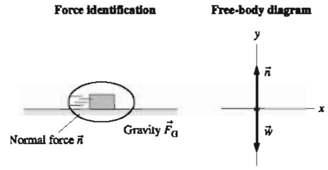
3.



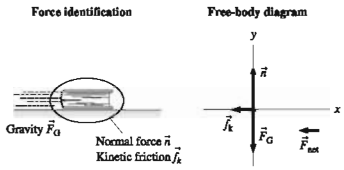
7. 3
9. $\frac{9}{25}$
11. 3.7 s
13. a. 4 m/s^2 b. 2 m/s^2
15. 0.25 kg
17. a. ≈0.05 N b. ≈100 N
19.



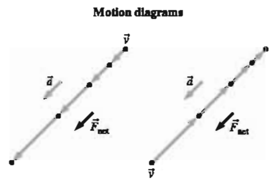
25.



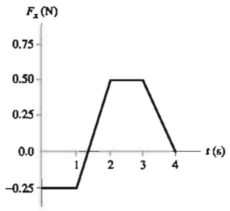
27.



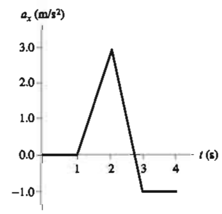
29.



31.

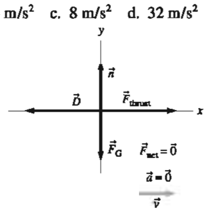


33.

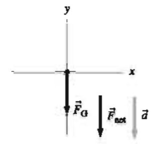


35. a. 16 m/s² b. 4 m/s² c. 8 m/s² d. 32 m/s²

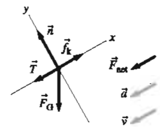
37.



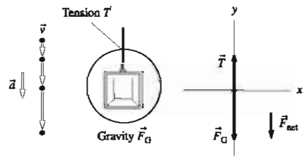
39.



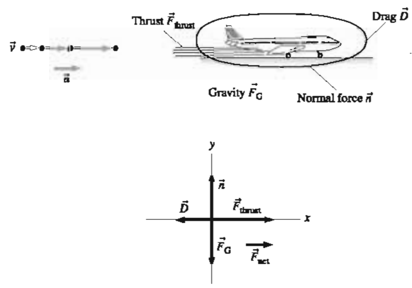
41.



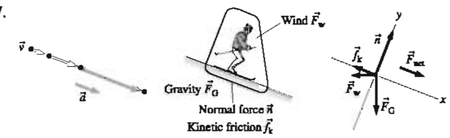
43.



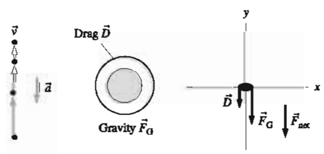
45.



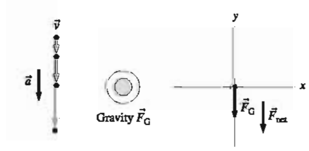
47.



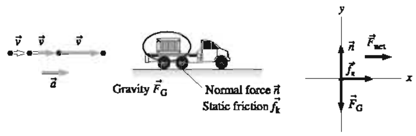
49.



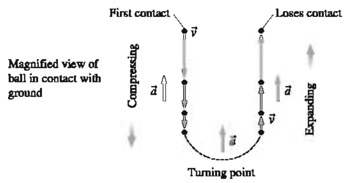
51.



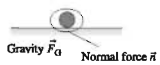
53.



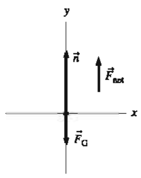
55. a.



b.

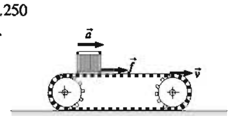


c.



Chapter 6

1. $T_1 = 86.7$ N, $T_2 = 50.0$ N
3. 147 N
5. a. $a_x = 1.0$ m/s^2, $a_y = 0$ b. $a_x = 1.0$ m/s^2, $a_y = 0$
7. a. $a_x = 0.40$ m/s^2, $a_y = 0.0$ m/s^2
   b. $a_x = 0.80$ m/s^2, $a_y = 0.0$ m/s^2
9. 4 m/s, 0 m/s^2
11. a. 490 N b. 490 N c. 740 N d. 240 N
13. 307 N
15. a. 590 N b. 740 N c. 590 N
17. 0.250
19. a.

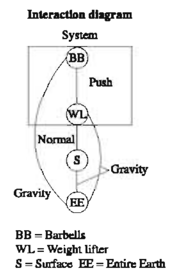


c. 4.9 m/s^2

21. 25 m/s
23. 2.55×10^3 m
25. 192 m/s
27. 4.0 m/s
29. 6397 N, 4376 N
31. a. 533 N b. 5.25×10^3 N
33. a. 7.8×10^2 N b. 1.05×10^3 N
35. a. 58.8 N b. 67.8° c. 79.0 N
37. 3.1 m
39. a. 5.2 m/s^2 b. 1.0×10^3 kg
41. a. 16.9 m/s b. 229 m
43. 0.68 m
45. Yes, no
51. 23 N
53. 51 m/s
55. $\frac{3}{8}$ in
57. Green
61. a. 0 N b. 2.2×10^2 N
63. b. 0.36 s
65. b. 3.5 m/s
67. $T = 144$ N
69. b. 12.3 m/s^2
71. a. $(2x)g$ b. 3.9 m/s^2
73. a. $v_0 e^{-\frac{6\pi\eta R t}{m}}$ b. 61 s
75. b. 134 s and 402 s c. No

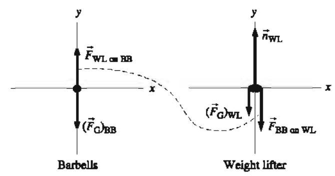
Chapter 7

1. a.

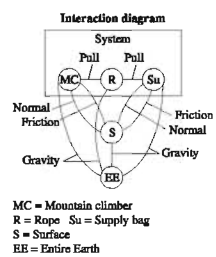


b. The system is the weightlifter and barbell

c.

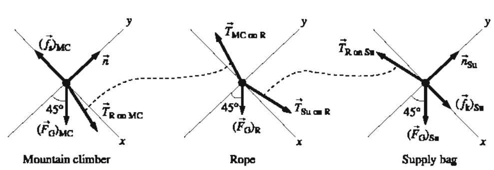


3. a.

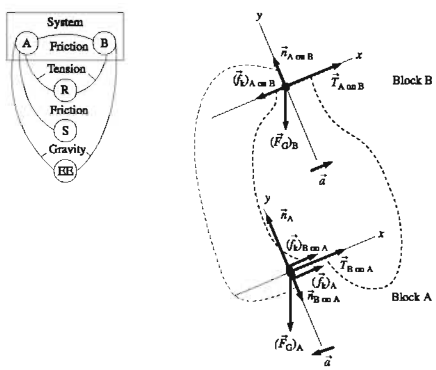


b. The system consists of the mountain climber, rope, and bag of supplies

c.

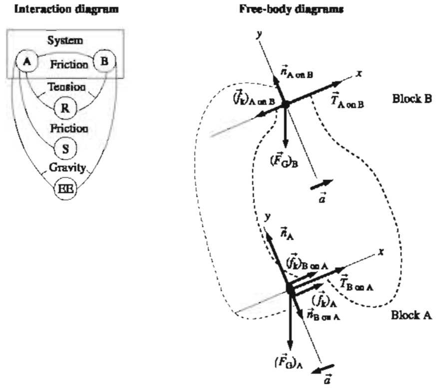


5. a. Interaction diagram   Free-body diagrams

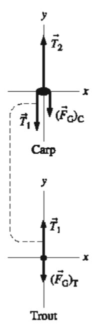


b. The system consists of the two blocks

c. Interaction diagram   Free-body diagrams

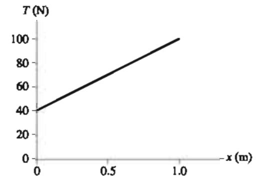


7. a. 7.8×10^2 N   b. 1.6×10^3 N
9. a. 3000 N   b. 3000 N
11. 5 kg
13. a.

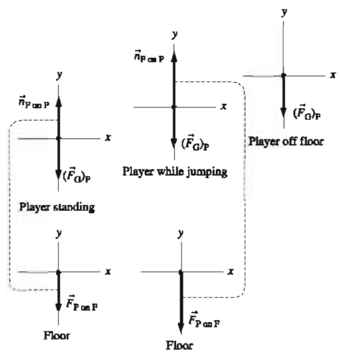


b. $T_2 > T_1 > (F_G)_T > (F_G)_C$

15. 9800 N
17. 67 N, 36°
19. 42 m apart
21.



23. 2.7×10^2 N
25. 6.533 m/s^2
27. a. 2.3×10^2 N   b. 0.20 m/s
29. 1.48 s
31. a. 32 N   b. 19.2 N   c. 16.0 N   d. 3.2 N
33. 1.75 s
35. 155 N
37. 100 N, 50 N, 50 N, 150 N, 50 N, $F = 50$ N
39. a. 1.83 kg   b. 1.32 m/s^2
41. a. 0.67 m   b. slides back down
43. a. 8.2×10^3 N   b. 4.8×10^2 N
45. 3.6×10^3 N
47. a.



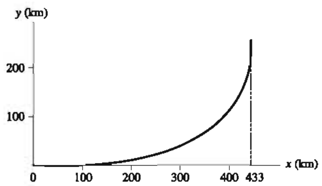
b. Yes   c. 3.96 m/s   d. 13.1 m/s^2 e. 980 N, 2290 N, 0 N
49. b. 0.47 m
51. $a_1 = \dfrac{2m_2 g}{4m_1 + m_2}$
53. b. 8.99 N

Chapter 8

1. 39 m
3. a. 56 h   b. 0.092°   c. Yes
5. 6.8 kN
7. 6.6×10^{15} rev/s
9. 2.01×10^{20} N
11. 1.58 m/s^2
13. 22 m/s
15. 3
17. 30 rpm
19. a. -1.96 rad/s^2 b. 1.60 s
21. $1.67x^2$
23. Crocodile food

25. 3.0 m
27. a. 24.0 h b. 0.223 m/s^2 c. 0 N
29. 179 N
31. 34 m/s
33. No
35. a. 5.00 N b. 30 rpm
37. Horizontal circle
39. a. 4.9 N b. 2.9 N c. 32 N
41. a. 3.2×10^2 N, 1.4 kN b. 5.7 s
43. 30 rpm
45. 45.0 s
47. 2.6 m
49. 13.1 N
51. a. 6.6 rad/s b. 43 N
53. b. $\omega = 20$ rad/s
55. a. $\theta = \frac{1}{2}\tan^{-1}(mg/F)$ b. 11.5%
57. a. Rotate the spacecraft 153.4° counterclockwise so that the exhaust is 26.6° below the positive x-axis. Fire with a thrust of 103,300 N for 433 s.
b.

t (s)	x (m)	y (m)
0	0	0
50	94.2	2.9
100	177	11.5
150	248	26
200	308	46.2
250	359	72
300	392	104
350	417	141.4
400	431	185
433	433	216.5
450	433	233.5
466	433	249.5



59. 3.7 rev
61. $T_1 = 14.2$ N and $T_2 = 8.3$ N
63. 37 km

Chapter 9

1. a. 1.5×10^4 kg m/s b. 8.0 kg m/s
3. 4 Ns
5. 1.5×10^3 N
7. 2.0 m/s to the right
9. 1.22 s
11. 9.6×10^2 N
13. 0.20 s
15. 5.0×10^2 kg
17. 4.8 m/s
19. 3.0×10^2 m/s
21. 0.20 m/s
23. $(-2\hat{\imath} + 4\hat{\jmath})$ kg m/s
25. (1.08, 0.63) kg m/s when thrown, (1.08, 0) kg m/s at the top, (1.08, −0.63) kg m/s just before hitting the ground
27. 25 m/s
29. 9.3×10^2 N
31. 0.50 m
33. 8.0×10^2 N
35. 2.13 m/s, up
37. a. 12.0 s b. 42° north of west
39. 14.1 m/s, 45° east of north
41. 4.4×10^2 m/s
43. 28 m/s
45. 4.0×10^2 m
47. a. 286 μs, 26 kN b. 0.021 m/s
49. 27.8 m/s
51. 1.46×10^7 m/s in the forward direction
53. 4.5 km
55. 14.0 u
57. b. and c. 1.40×10^{-22} kg m/s in the direction of the electron
59. 0.85 m/s, 72° below $+x$
61. 1.97×10^3 m/s
63. c. $(v_{1x})_2 = 6.0$ m/s
65. c. $(v_{fx})_1 = -12$ m/s
67. 13.6 m
69. 1226 m/s
71. 8

Chapter 10

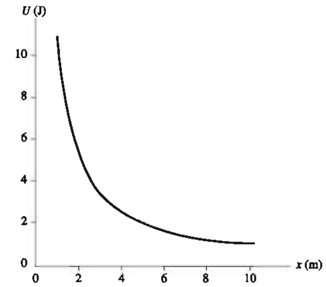
1. The bullet
3. 112 km/h
5. a. 25.1 m b. 10 m/s c. 22 m/s
7. 2.0
9. 7.7 m/s
11. a. 1.40 m/s b. 30°
13. 1.41 m/s
15. 98 N/m
17. a. 49 N b. 1.45×10^3 N/m c. 3.4 cm
19. 10 J
21. 2.0 m/s
23. 3.0 m/s
25. 0.86 m/s and 2.9 m/s
27. a. $0.048v_0$ b. 95%
29. a. Right b. 17.3 m/s c. $x = 1.0$ m and 6.0 m
31. 63 m/s
33. Yes
35. a. No b. 17.3 m/s
37. c. 2.0×10^2 N/m d. 19 m/s
39. $v_0/\sqrt{2}$
41. 51 cm
43. 25.8 cm
45. a. 0.20 m b. 0.10 m
47. 93 cm
49. 43 m
51. a. $\sqrt{\dfrac{(m + M)kd^2}{m^2}}$ b. 2.0×10^2 m/s c. 0.9975
53. a. $\frac{3}{2}R$ b. 15 m
55. a. 3.5 m b. No, height
57. a. 100 g ball: −5.3 m/s; the 200 g ball: 1.7 m/s b. −0.67 m/s
59. a. $x = 1$ m and $x = 7$ m b. 4.0 m/s c. 6.9 m/s
61. a. $x_1 = \dfrac{\pi}{3}$ and $x_2 = \dfrac{2\pi}{3}$ b. $\dfrac{\pi}{3}$: unstable, $\dfrac{2\pi}{3}$: stable
65. c. 36 N/m
67. c. 2.6 m/s
69. $\theta = 80.4°$
71. a. 1.46 m b. 19.6 cm
73. a. 4.6 cm b. $v_{A3} = 1.33$ m/s and $v_{B3} = 5.3$ m/s
75. 100 g ball rebounds to 79°, 200 g ball rebounds to 14.7°

Chapter 11

1. a. 15.3 b. −4.0 c. 0
3. a. −30 b. 0
5. a. 162° b. 90°
7. a. 12.0 J b. −6.0 J
9. 0 J
11. 1.250×10^4 J by the gravity, -7.92×10^3 J by $\vec{T}_1$, -4.58×10^3 J by $\vec{T}_2$
13. AB: 0 J, BC: 0 J, CD: −4.0 J, DE: +4.0 J, EF: −3.0 J
15. 7.35 m/s, 9.17 m/s, 9.70 m/s
17. 8.0 N

19. -20 N at $x = 1$ m, 30 N at $x = 4$ m

21. a.

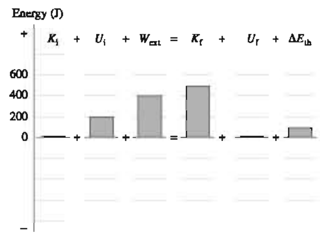


b. 2.5 N, 0.40 N, and 0.156 N

23. 1360 m/s

25. b. 5.5×10^2 J

27.



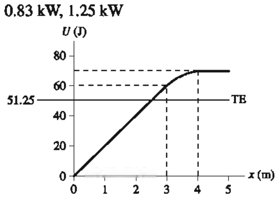
29. 6.26 m/s

31. a. 176 J b. 59 W

33. Night light

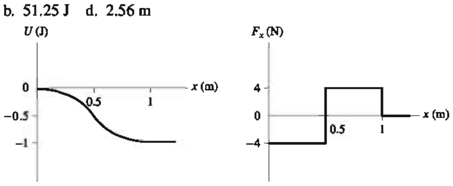
35. b. 0.41 kW, 0.83 kW, 1.25 kW

37. a.



b. 51.25 J d. 2.56 m

39.



41. a. $-98{,}000$ J b. 108,000 J c. 10,000 J d. 4.5 m/s

43. a. and b. 4.0 m/s

45. 2.4 m/s

47. 0.037

49. a. 1.70 m/s b. No

51. a. $W_T = 0.57$ kJ, $W_g = -196$ J, $W_n = 0$ J b. 38.5 J

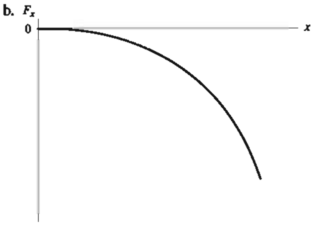
53. a. 2.16 m/s b. 0.0058

55. a. 9.90 m/s b. 9.39 m/s c. 93.9 cm d. 10

57. a. $\sqrt{2gh}$ b. $h - \mu_k L$

59. a. N/m^3

b. F_x



c. $\frac{1}{4}qx^4$ d. 10 m/s

63. 5.5×10^4 liters

65. 18 hp

67. 55.5 m/s

69. c. 10.9 N

71. c. 58.8 N, 1.28 m/s

73. 10.0 m/s

75. a. 460 N b. 16.2 m/s

77. 24 W

Chapter 12

1. 13.2 m/s
3. a. 0.057 m/s^2 b. 7.9 m
5. 4.67×10^6 m
7. $x_{cm} = 6.7$ cm, $y_{cm} = 8.3$ cm
9. 2.57×10^{29} J
11. 2.4 m/s
13. 1.75 J
15. a. 0.057 m, 0.057 m b. 0.0015 kgm^2
17. a. 6.9 kgm^2 b. 4.1 kgm^2
19. -0.20 Nm
21. 176 N
23. 12.5 kNm
25. 8.0 Nm
27. 0.28 Nm
29. a. 1.75×10^{-3} Nm b. 50 rev
31. 11.76 Nm
33. 1.40 m
35. a. 6.4×10^2 rpm b. 40 m/s c. 0 m/s
37. a. 88 rad/s b. $\frac{2}{7}$
39. a. (21, out of the page) b. (24, into the page)
41. a. $-\hat{j}$ b. $\vec{0}$
43. a. $n\hat{i}$ b. $2\hat{j}$ c. $1\hat{k}$
45. $50\hat{k}$ Nm
47. $1.20\hat{k}$ kgm^2/s or (1.20 kgm^2/s, out of page)
49. (0.025 kgm^2/s, into page) (or $-0.025\hat{i}$ kgm^2/s)
51. 28 m/s
53. 20 cm, 0 cm
55. a. 0.010 kgm^2 b. 0.030 kgm^2
59. $\frac{1}{6}ML^2$
61. 51°
63. Yes
65. Yes because $d_{max} = 25L/24$
67. a. 3.4 m/s b. 3.4 m/s
69. a. 177 s b. 5.6×10^5 J c. 1.4×10^5 W d. 1.30 kNm
71. a. $a = \dfrac{m_2 g}{m_1 + m_2}$, $T = \dfrac{m_1 m_2 g}{m_1 + m_2}$

b. $a = \dfrac{m_2 g}{m_1 + m_2 + \frac{1}{2}m_p}$ $T_1 = \dfrac{m_1 m_2 g}{m_1 + m_2 + \frac{1}{2}m_p}$

$T_2 = \dfrac{m_2(m_1 + \frac{1}{2}m_p)g}{m_1 + m_2 + \frac{1}{2}m_p}$

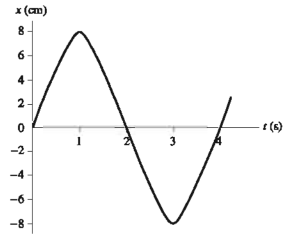
73. a. 57.9 m b. 0.23 rad/s
75. a. $\frac{m}{m+M}L$ b. Center of mass
77. a. $\sqrt{2g/r}$ b. $\sqrt{8gR}$
79. $\frac{20Tr}{13MR^2}$
81. a. No b. 2000 m/s c. 4000 m/s
83. 3.9×10^2 m/s
85. a. 43 cm
87. 50 rpm
89. 4.0 rpm
91. $2.7(R - r)$
93. $\frac{1}{5}v_0$ to the right
95. a. 137 km b. 8.6×10^6 m/s

Chapter 13

1. 6.00×10^{-4}
3. 2.18
5. 2.3×10^{-7} N
7. a. 274 m/s^2 b. 5.90×10^{-3} m/s^2
9. 2.43 km
11. a. 3.0×10^{24} kg b. 0.89 m/s^2
13. 60.2 km/s
15. 4.21×10^4 m/s
17. 4.37×10^{11} m, 1.74×10^4 m/s
19. a. 1.48×10^{25} kg b. 5.2×10^{30} kg
21. 2.9×10^9 m
23. 4.2 h
25. 46 kg and 104 kg
27. (11.7 cm, 0 cm)
29. $3.0 \times 10^{-7}\hat{j}$ N
31. -1.96×10^{-7} J
33. a. 3.02 km/s b. 3.13 km/s c. 3.6%
35. a. 2.8×10^6 m b. 3.7 km/s
37. a. 11.3 km/s b. 8.94 km/s
39. Yes
41. 12.2 km/s
43. $0.516(GM/R)^{1/2}$, $1.032(GM/R)^{1/2}$
45. 3.71×10^5 m/s
47. 1.17×10^{11} J
49. a. 5.8×10^{22} kg b. 1.33×10^6 m
51. 8.67×10^7 m
53. a. $y = (q/p)x + (\log C)/p$ b. Linear c. q/p e. 1.996×10^{30} kg
55. a. 6.3×10^4 m/s b. 1.33×10^{12} m/s^2 c. 1.33×10^{12} N d. 9.5×10^4 orbits/minute e. 1.50×10^6 m
57. 9.33×10^{10} m
59. 3.71 km/s
61. 4.49 km/s
63. a. No b. Yes
65. c. 6.21×10^7 m
67. c. 1680 m/s
69. b. 282 days
71. a. 0° b. 4.04 N
73. a. 24 years b. 12.3 km/s, 4.1 km/s
75. b. 7730 m/s, 10,160 m/s c. 2.17×10^{10} J d. 1600 m/s, 3070 m/s e. 3.43×10^9 J f. 2.513×10^{10} J
77. a. $-\frac{GmM}{\sqrt{x^2 + R^2}}$ b. $GmM\frac{x}{(x^2 + R^2)^{3/2}}$

Chapter 14

1. 2.27 ms
3. a. 12.7 cm b. 9.0 cm
5. a. 20 cm b. 0.25 Hz c. $-60°$
7.



9. $(8.0 \text{ cm})\cos\left[(\pi \text{ rad/s})t + \frac{\pi}{2}\text{rad}\right]$
11. a. 2.8 s b. 1.41 s c. 2.0 s d. 1.41 s
13. a. 0.50 s b. 4π rad/s c. 5.54 cm d. 0.45 rad e. 70 cm/s f. 8.8 m/s^2 g. 0.049 J h. 3.8 cm

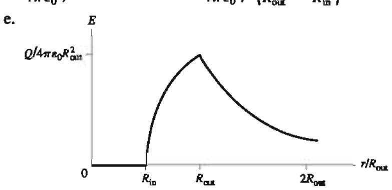
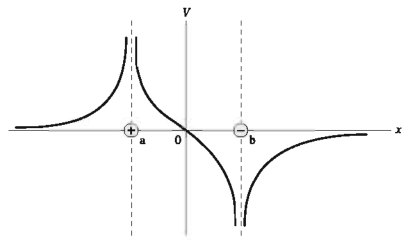
49. $(\eta/2\epsilon_0)\hat{j}$, $\vec{0}$ N/C, $(\eta/2\epsilon_0)\hat{j}$, $-(\eta/2\epsilon_0)\hat{j}$
51. a. $\dfrac{\lambda}{2\pi\epsilon_0}\dfrac{\hat{r}}{r}$ b. $\dfrac{3\lambda}{2\pi\epsilon_0}\dfrac{\hat{r}}{r}$
53. a. $\dfrac{1}{4\pi\epsilon_0}\dfrac{Q}{r^2}\hat{r}$ b. $\vec{E} = \vec{0}$ c. $\dfrac{1}{4\pi\epsilon_0}\dfrac{Q}{r^2}\left(\dfrac{r^3 - R_{in}^3}{R_{out}^3 - R_{in}^3}\right)\hat{r}$
    e.



55. a. $\dfrac{\lambda L^2 dy}{4\pi\epsilon_0[y^2 + (L/2^2)]}$ b. $\dfrac{\lambda L}{4\epsilon_0}$
57. a. $C = \dfrac{Q}{4\pi R}$ b. $\dfrac{1}{4\pi\epsilon_0}\dfrac{Q}{Rr}\hat{r}$ c. Yes
59. a. $\dfrac{Q}{4\pi\epsilon_0 R^2}$ b. $\dfrac{3Qr^3}{2\pi R^6}$

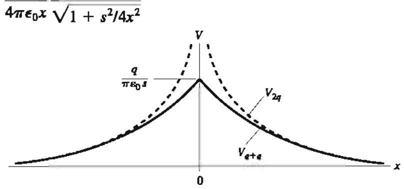
Chapter 29

1. 1.38×10^5 m/s
3. 70,711 m/s
5. -2.24×10^{-19} J
7. 3.87×10^{-6} J
9. a. -1 μJ b. 1 μJ
11. 4.38×10^5 m/s
13. 11.4 V
15. a. Higher b. 3340 V
19. a. 200 V b. 3.5×10^{-10} C
21. a. 1000 V b. 1.39×10^{-9} C c. 7.0×10^6 m/s
23. a. 1.80 kV, 1.80 kV, 0.90 kV b. 0 V, -0.90 kV
25. a. 27 V b. -4.3×10^{-18} J
27. 0 V
29. $x = 3$ cm and 6 cm
31. a. Positive, negative b. 1
    c.



33. 0 V
35. 1.44×10^{-3} N
37. a. $+103$ V b. $5.40 \times 10^4\hat{\imath}$ N/C
39. 1.77 cm/s, 1.06 cm/s
41. 0.49 m/s
43. a.

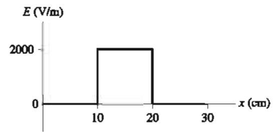
    b. SHM c. 3.2×10^{-7} J d. 2.5 m/s
45. b. 2.96×10^5 m/s
47. a. 0.85 m b. 2.6 m
49. 8.0×10^7 m/s
51. 0.28 rad/s
53. 4.2×10^{-10} C
55. 6.8 fm
57. a. Yes c. 8.21×10^8 m/s
59. a. 2.1×10^{-10} C, 3.0 kV/m, 15 V b. 2.1×10^{-10} C, 3.0 kV/m,
    30 V c. 2.1×10^{-10} C, 0.75 kV/m, 3.8 V
61. a. V_0/R b. 100 kV/m
63. a. Charge moves to outside surface of sphere. b. 8.3 μC
    c. Zero inside, 3.3×10^6 V/m outside
65. Point b is higher, 2.1 kV
67. a. $\dfrac{2q}{4\pi\epsilon_0 x}\dfrac{1}{\sqrt{1 + s^2/4x^2}}$
    b.



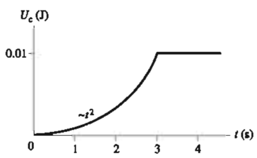
69. $(Q/4\pi\epsilon_0 L)\ln[(x + L/2)/(x - L/2)]$
71. $Q/4\pi\epsilon_0 R$
73. b. q_1 and q_2 are 10 nC and 30 nC
75. b. 6.0 cm
77. 1.93×10^{-14} m
79. $v_C = 9.8$ cm/s, $v_D = 4.9$ cm/s
81. a. $\dfrac{qd\,dq}{A\epsilon_0}$
83. a. $\dfrac{\lambda}{4\epsilon_0 R}\left(1 + \dfrac{2\ln(3)}{\pi}\right)$
85. $\dfrac{2Q/L}{4\pi\epsilon_0}\ln\left(\dfrac{L}{2R} + \sqrt{1 + \left(\dfrac{L}{2R}\right)^2}\right)$

Chapter 30

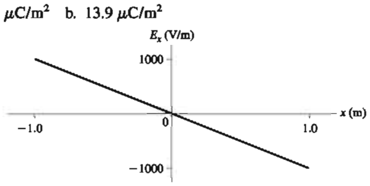
1. −200 V
3. −300 V
5. 1.5×10^{-6} J
7. 12 V
9. 10 kV/m to the left
11.



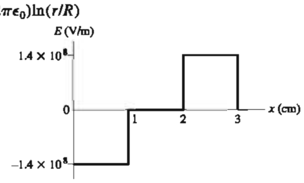
13. −1.0 kV/m
15. a. −150 V/m b. −75 V/m
17. a. 7.1 pF b. ±0.71 nC
19. 3.0 V
21. 5.0×10^{-9} F
23. 3.0 μF
25. 150 μF, in series
27. 15.0×10^{-6} C
29.



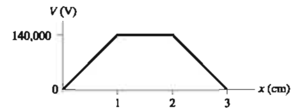
31. 1.19 kV/m
33. a. 1.29 nF b. 3.2 kV
35. a. 83 μC/m^2 b. 13.9 μC/m^2
37. a.



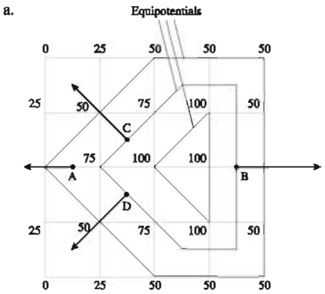
b. 1000 V/m, 127° ccw
39. $V_0 - (\lambda/2\pi\epsilon_0)\ln(r/R)$
41. a.



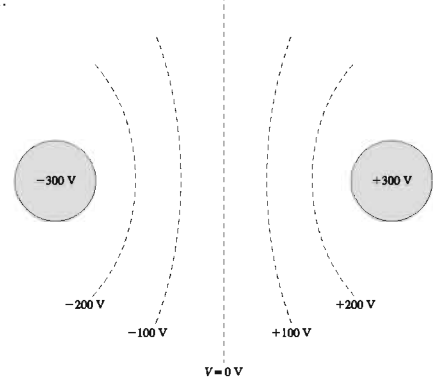
b.



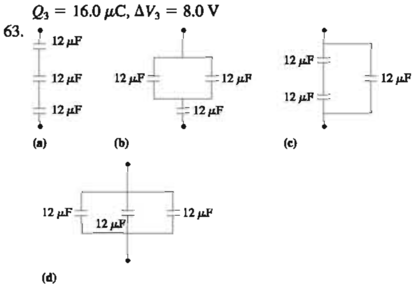
43. $(Q/2\pi\epsilon_0 R^2)[1 - z/(R^2 + z^2)^{1/2}]$
45. Point 1: 3750 V/m, downward; point 2: 7500 V/m, upward
47. 1000 V/m, 127° ccw from the $+x$-axis
49. a.



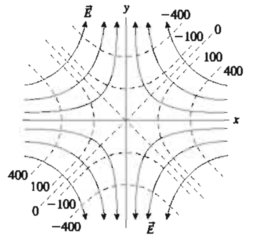
b. $\vec{E}_A =$ (500 V/m, left), $\vec{E}_B =$ (1000 V/m, right),
$\vec{E}_C =$ (707 V/m, 45° above straight left),
$\vec{E}_D =$ (707 V/m, 45° below straight left)
51.



53. a. 2 b. 2
55. a. ±32 pC, 9.0 V b. ±16.0 pC, 9.0 V
57. a. NC b. $\dfrac{C}{N}$
59. 8.9 μF
61. $Q_1 = 4.0\ \mu$C, $\Delta V_1 = 1.0$ V; $Q_2 = 12.0\ \mu$C, $\Delta V_2 = 1.0$ V; $Q_3 = 16.0\ \mu$C, $\Delta V_3 = 8.0$ V
63.



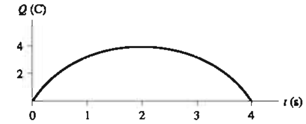
65. a. $\frac{3}{2}C$ b. 0
67. a. $Q_1 = 0.83$ mC, $Q_2 = Q_3 = 0.67$ mC, $\Delta V_1 = 55$ V, $\Delta V_2 = 34$ V, $\Delta V_3 = 22$ V
69. $Q_1' = 33\ \mu C$, $Q_2' = 67\ \mu C$, $\Delta V_1 = 3.3\ V = \Delta V_2$
71. a. 5.7×10^{-7} J b. 11.4×10^{-7} J
c. Work was done on the capacitor.
73. 22 μF
77. $C_0\left(\frac{2\kappa}{1+\kappa}\right)$
79. b. 0.022 mm
81. a., c.



b. $-200(x\hat{\imath} - y\hat{\jmath})$ V/m
83. $-pR^2/4\epsilon_0$
85. a. $\frac{2\pi\epsilon_0}{\ln(R_2/R_1)}$ b. 31 pF/m

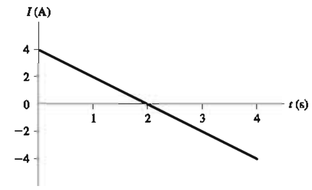
Chapter 31

1. 7.5×10^{-5} m/s
3. 0.93 mm
5. Aluminum
7. 5.1×10^{-12} C/m^2
9. 0.31 N/C
11. a. 0.80 A b. 7.0×10^7 A/m^2
13. a. 2.8×10^6 A/m^2 b. 0.56 A
15. 3.0×10^3 C, 1.88×10^{22} electrons
17. 2.6 mA
19. 4.2×10^6 A/m^2
21. 3.8×10^{-14} s, 2.5×10^{-14} s
23. 0.159 N/C
25. Nichrome
27. $\frac{1}{2}$
29. a. 0.50 C/s b. 1.5 J c. 0.75 W
31. a. 0.087 Ω b. 3.5 Ω
33. 1.5 mV
35. 2.3 mA
37. a. 3.6 m b. 380
39. 0.64 mm
43. a. 75 nA b. 133 s
45. 23 mA
47. a. 120 C b. 0.45 mm
49. 1/4
51. a. $E = \frac{I}{2\pi\sigma L r}$ b. $E_{inner} = 4.0 \times 10^{-4}$ V/m, $E_{outer} = 1.59 \times 10^{-4}$ V/m
53. a.

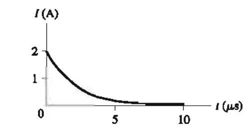


b. $4 - 2t$

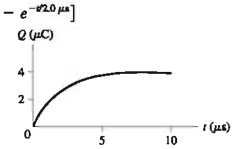
c.



55. a.



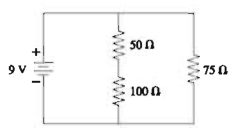
b. $(4.0\ \mu C)[1 - e^{-t/2.0\ \mu s}]$
c.



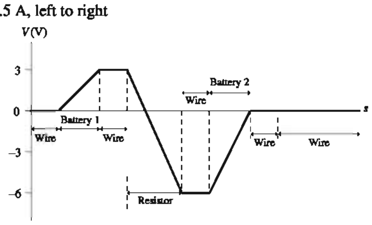
57. 2.0 A, 5.0×10^{-5} m/s
59. 7.2 mm
61. a. 10 V/m b. 6.7×10^6 A/m^2 c. 0.62 mm
63. 1.80×10^3 C
65. $4R$
67. 0.87 V
69. 10.4 A
71. a. 1.15×10^5 m/s b. 1.5 nm
73. a. $Q\Delta V_{bat}$ b. Heating the wire c. $I\Delta V_{bat}$ d. 1.80 W

Chapter 32

1.

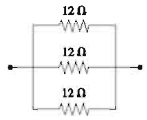


3. 5 A, toward the junction
5. a. 0.5 A, left to right
b.

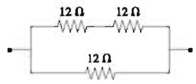


7. a. 9.60 Ω, 12.5 A
9. 23.6 μm
11. a. 11.6 A b. 10.4 Ω
13. Greater than
15. 18.8 W, 18.8 W
17. 0.65 Ω, 3.5 W
19. 1.18 Ω
21. Less than
23. 34 Ω
25. 54.5 Ω

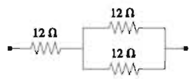
27. 9 V, 7 V, 1 V, and 0 V
31. 2 ms
33. a. 36 μC, 0.36 A b. 22 μC, 0.22 A c. 4.9 μC, 49 mA
35. 18.0 μF
37. A > D > B > F > C = E
39. 78 mΩ
41. a.



b.

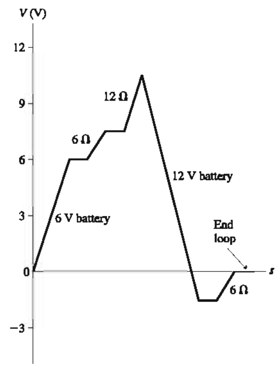


c.

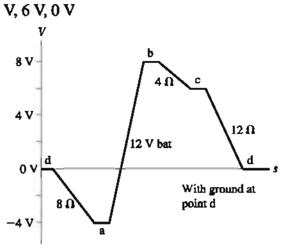


d.

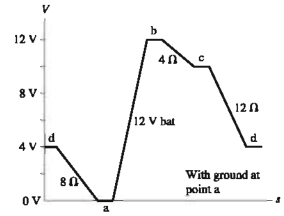
43. a. Counterclockwise b. 6 Ω c. 0.38 W
d.



45. 45 W in the 5 Ω resistor, 20 W in the 20 Ω resistor
47. $R = 20\ \Omega$, 60 V
49. a. r b. 20 W
51. a. −4 V, 8 V, 6 V, 0 V
b.



c. 0 V, 12 V, 10 V, 4 V



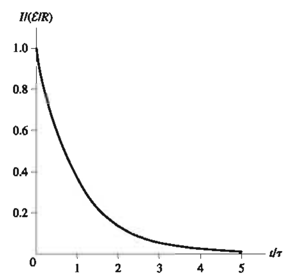
53. The compact fluorescent bulb is cheaper.
55. a. 0.231 A b. 0.214 A c. 7.4% d. No
57. 900 Ω
59. 9.95 kΩ
61.

Resistor	Potential difference (V)	Current (A)
3 Ω	6.0	2.0
4 Ω	6.0	1.5
48 Ω	6.0	1.2
16 Ω	6.0	3.8

63.

Resistor	Potential difference (V)	Current (A)
24 Ω	6.00	0.25
3 Ω	3.00	1.00
5 Ω	3.75	0.75
4 Ω	2.25	0.56
12 Ω	2.25	0.19

65. 0.12 A, left to right
67. 150 V, on top
69. 2.1 A, left to right
71. 73 Ω
73. a. $\mathcal{E}$ b. $C\mathcal{E}$ c. $+dQ/dt$ d. $\frac{\mathcal{E}}{R}e^{-t/\tau}$



75. 23 mJ
79. 5.1 kΩ

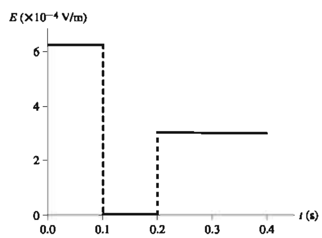
Chapter 33

1. (2.0 mT, into the page), (4.0 mT, into the page)
3. a. $1.60 \times 10^{-15}\hat{k}$ T b. 0 T c. 0 T
5. $-1.13 \times 10^{-15}\hat{k}$ T
7. 6.3×10^{6} m/s in the $+z$-direction
9. 4.0 cm, 0.40 mm, 20 μm to 2.0 μm, and 0.20 μm
11. a. 20 A b. 1.60×10^{-3} m
13. a. $2.0 \times 10^{-4}\hat{\imath}$ T
b. $4.0 \times 10^{-4}\hat{\imath}$ T
c. $2.0 \times 10^{-4}\hat{\imath}$ T

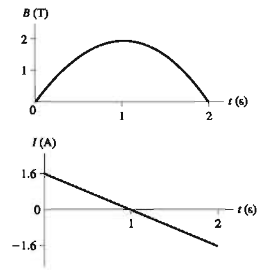
15. a. $0.025\ \text{A m}^2$ b. $1.48\ \mu\text{T}$
17. 2.1 cm
19. 0.071 T m
21. 1.0 A
23. 1.26×10^{-6} T m
25. 2.4 kA
27. a. $-8.0 \times 10^{-13}\hat{k}$ N b. $5.7 \times 10^{-13}(-\hat{j} - \hat{k})$ N
29. 1.61×10^{-3} T
31. 1.25 T
33. $2.9 \times 10^{28}\ \text{m}^{-3}$
35. 0.025 N, to the right
37. $3.0\ \Omega$
39. 7.5×10^{-4} N m
41. a. 1.26×10^{-11} N m b. Rotated $\pm 90°$
43. (5.2×10^{-5} T, out of the page); 0 T
45. 750 A
47. 7.9×10^{-5} T, into page
49. #18 wire, 4.1 A
51. a. 1.13×10^{10} A b. $0.014\ \text{A/m}^2$ c. The current density in the earth is much less than the current density in the wire.
53. $\mu_0 I/4R$
55. 0; $(\mu_0 I/2\pi r)[(r^2 - R_1^2)/(R_2^2 - R_1^2)]$; $\mu_0 I/2\pi r$
57. 1.50 mT, 30° ccw from $+x$-axis
59. 2.9×10^{-3} T
61. a. ($2.4 \times 10^{10}\ \text{m/s}^2$, down) b. ($2.2 \times 10^{11}\ \text{m/s}^2$, up)
63. a. 4.6×10^{-13} J b. 2850
65. 2.10 T
67. 2.0 A
69. 8.6 mT, down
71. a. $\dfrac{\pi R^2 \rho g}{20B}$ b. 9.6 A
73. 12.5 T
75. 57 nm
77. 1.0 cm
79. $\dfrac{\mu_0 \omega Q}{2\pi R}$
81. a. $\dfrac{3I}{2\pi R^2}$ b. $\dfrac{\mu_0}{2\pi}\dfrac{Ir^2}{R^3}$ c. Yes
83. a. Horizontal and to the left above the sheet; horizontal and to the right below the sheet b. $\frac{1}{2}\mu_0 J_s$

Chapter 34

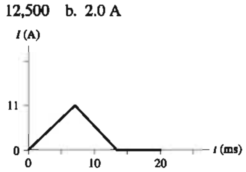
1. 2.0×10^4 m/s
3. a. 4.0 m/s b. 2.2 T
5. 6.3×10^{-5} Wb in both cases
7. Increasing
9. ccw
11. a. 3.9 mV, 20 mA cw b. 3.9 mV, 20 mA cw c. 0
13. 3.1 V
15.



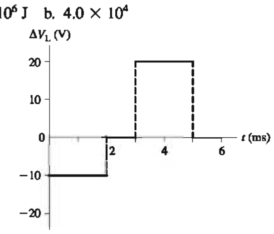
17. a. $4.8 \times 10^4\ \text{m/s}^2$, up b. 0 c. $4.8 \times 10^4\ \text{m/s}^2$, down d. $9.6 \times 10^4\ \text{m/s}^2$, down
19. 1.0 ms
21. 9.5×10^{-5} J
23. 250 kHz to 360 kHz
25. $900\ \Omega$
27. 3.5×10^{-4} Wb
29. b.



31. 42 mV
33. 8.7 T/s
35. a. 0.0050 V b. 0.0100 V
37. $44\ \mu\text{A}$
39. a. $0\ \mu\text{A}$ b. $160\ \mu\text{A}$ c. $0\ \mu\text{A}$
41. a. $0\ \mu\text{A}$ b. $79\ \mu\text{A}$
43. a. 0.93 V b. 0 V
45. a. 12,500 b. 2.0 A
47. a.

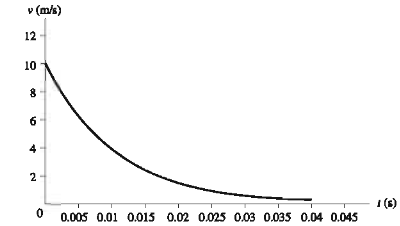


b. 11 A when halfway in
49. a. 0.20 A b. 4.0×10^{-3} N c. 11°C
51. a. $(4.93 \times 10^{-3}) f \sin(2\pi f t)$ A b. 405 Hz; not feasible
53. a. $(vlB\cos\theta)/R$ b. $(mgR\tan\theta)/(l^2B^2\cos\theta)$
55. 2.5×10^{-4} V
57. 12 V
59. $(R^2/2r)(dB/dt)$
61. 400
63. 0.89 mm
65. a. 1.25×10^6 J b. 4.0×10^4
67.



69. a. $-L\omega I_0 \cos\omega t$ b. 1.3×10^{-3} A
71. a. 0.63 ms b. 25 V
73. $0.707Q_0$
75. 2.0 mH, $0.13\ \mu\text{F}$
77. a. 50 V b. Open S_1 and close S_2 at 0.0625 s, then open S_2 at 0.1875 s.
79. a. 1.0 A b. 0 A c. 3.0 A
81. $(\mu_0 v I/2\pi)\ln[(d + l)/d]$
83. a. cw b. $10t$ V, 35 A c. 1.0 V, 35 A

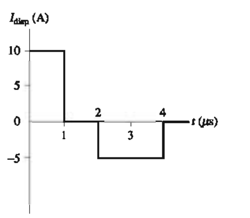
85. a. $v_0\exp[-(l^2B^2/mR)t]$
b.



87. a. $(\mu_0/2\pi)\ln(r_2/r_1)$ b. 0.36 μH/m

Chapter 35

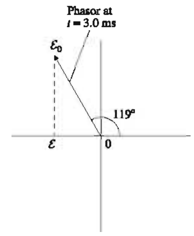
1. a. (2.0×10^6 m/s, 45° from the y-axis)
b. (1.47×10^6 m/s, 16.2° from the y'-axis)
3. $-1.0 \times 10^6\hat{j}$ V/m, $1.11 \times 10^{-5}\hat{k}$ T
5. 16.3°
9. 1.0×10^6 V/s
11. 22 μA
13. 6.0×10^5 V/m
15. a. 10.0 nm b. 3.00×10^{16} Hz c. 6.67×10^{-8} T
19. 1.2×10^{-10} W/m^2
21. a. 2.2×10^{-6} W/m^2 b. 0.041 V/m
23. 3.3×10^{-6} N
25. 60°
27. 131 W/m^2
29. (1.7×10^6 V/m, left)
31. a. (0.10 T, into the page) b. 0 V/m, (0.10 T, into the page)
33. 1.0×10^7 m/s parallel to the current
35. a. 0.94 V/m b. 10.0 T
37. b. 1.5×10^{-13} A
39.



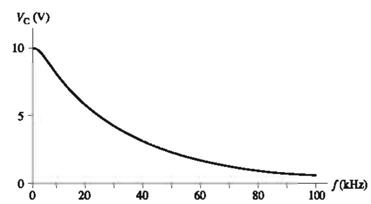
41. a. $a = -14.6$, $B_0 = 6.8 \times 10^{-2}$ b. $-260\hat{i} + 140\hat{j} - 200\hat{k}$ W/m^2
43. 2800 V/m, 9.3×10^{-6} T
45. 162 s
47. a. 8.3×10^{-26} W/m^2 b. 7.9×10^{-12} V/m
49. 9.4×10^7 W/m^2
51. a. 5.78×10^8 N, 1.64×10^{-14}
53. 4.9×10^7 W/m^2
55. Yes
57. $(-6.0\hat{i} + 1.0\hat{k}) \times 10^5$ N/C
59. 20 V
61. a. IR/L; $\mu_0 I/2\pi r$ b. ($I^2R/2\pi rL$, radially inward)

Chapter 36

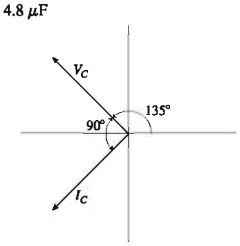
1. a. 2.4×10^2 rad/s b. -10.4 V
3.



5. a. 50 mA b. 50 mA
7. a. 188 mA b. 1.88 A
9. a. 80 kHz b. 0 V
11. a. 95 pF b. 660 μA
13. 1.59 μF
15. $V_R = 6.0$ V, $V_C = 8.0$ V
17. a. 10.0 Hz b. 4.47 V, 3.53 V, 2.24 V
19. a. 0.80 A b. 0.80 mA
21. a. 3.2×10^4 Hz b. 0 V
23. a. 200 kHz b. 141 kHz
25. 1.27 μF
27. a. 70 Ω, 72 mA, −44° b. 50 Ω, 100 mA, 0° c. 62 Ω, 80 mA, 37°
29. 9.6 Ω
31. 4.0×10^2 W
33. 44 Ω
35. a. $1/\sqrt{3}RC$ b. $(\sqrt{3}/2)\mathcal{E}_0$ c. 3630 rad/s
37. a. 9.95 V, 9.57 V, 7.05 V, 3.15 V, 0.990 V
b.

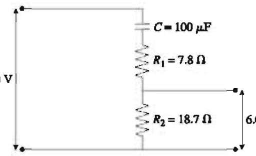


43. 44 Hz
45. a. 50 Hz b. 4.8 μF
c.

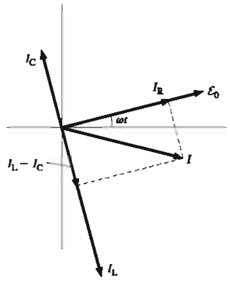


47. a. $\mathcal{E}_0/\sqrt{R^2+\omega^2L^2}$, $\mathcal{E}_0R/\sqrt{R^2+\omega^2L^2}$, $\mathcal{E}_0\omega L/\sqrt{R^2+\omega^2L^2}$
b. $V_R \to \mathcal{E}_0$, $V_R \to 0$ c. Low pass d. R/L
49. a. 1.62 A b. −17.7° c. 137 W
51. a. 3.2×10^4 rad/s, 5.0×10^3 Hz b. 10.0 V, 32 V
53. 0.173 A
55. a. 3.6 V b. 3.5 V c. −3.6 V
59. a. 11.64 pF b. 1.49×10^{-3} Ω
61. 14.4 W by 40 W; 9.6 W by 60 W; 100 W by 100 W
63. a. 0.833 b. 100 V c. 12.5 Ω d. 320 μF

65.



67. a. $2.5\ \Omega$ b. 8.1 kHz
69. b. 10.0 V, 11.55 V
71. b. ∞, ∞ c. $\sqrt{1/LC}$
d.



Chapter 37

1. $x_1' = 5.0$ m/s, $t_1' = 1.0$ s; $x_2' = 5.0$ m/s, $t_2' = 5.0$ s
3. $v_{sound} = 345$ m/s, $v_{sprinter} = 15$ m/s
5. a. 13 m/s b. 3.0 m/s c. 9.4 m/s
7. $c = 3.0 \times 10^8$ m/s
9. 167 ns
11. 2.0 μs
13. Bolt 2 20 μs before bolt 1
15. Yes
17. $0.866c$
19. a. $0.9965c$ b. 59.8 ly
21. 46 m/s
23. Yes
25. 4600 kg/m^3
27. 3.0×10^6 m/s
29. $x = 8.3 \times 10^{10}$ m, $t = 330$ s
31. $0.36c$ in $-x$-direction
33. $0.71c$
35. $0.80c$
37. $0.707c$
39. a. 1.8×10^{16} J b. 9.0×10^9
41. $0.943c$
43. $u_{50\text{ final}} = 1.33$ m/s to the right, $u_{100\text{ final}} = 3.33$ m/s to the right
45. $u_{1\text{ initial}} = 4.0$ m/s to the right, $u_{2\text{ initial}} = 2.0$ m/s to the left
47. 11.2 h
49. a. No b. 67.1 y
51. a. $0.80c$ b. 16 y
53. 0.78 m
55. a. 8.5 ly, 17 y b. 7.4 ly, 15 y c. Both
57. $0.96c$
59. 3.1×10^6 V
61. a. $0.98c$ b. 8.5×10^{-11} J
63. b. Lengths perpendicular to the motion are not affected.
65. a. $u_y' = u_y/\gamma(1 - u_x v/c^2)$ b. $0.877c$
67. $3.87mc$
69. $0.786c$
71. a. 7.6×10^{16} J b. 0.84 kg
73. 7.5×10^{-13} J
75. 1 pm
77. 22 m
79. $0.85c$
81. Yes

Chapter 38

1. $6.3 \times 10^{10}\ s^{-1}$
3. 5.0×10^{-3} T, out of page
5. 0.52 μm
7. a. 5.9×10^6 m/s b. 3.1×10^7 m/s c. Alpha particle
9. a. 71 eV b. -14 eV c. 5.0 keV
11. 75 eV
13. a. 4 electrons, 4 protons, 5 neutrons
b. 6 electrons, 7 protons, 7 neutrons
c. 4 electrons, 6 protons, 7 neutrons
15. a. ^{10}Be b. $^{11}C^{++}$
17. a. 79 electrons, 79 protons, 118 neutrons b. 2.29×10^{17} kg/m^3
c. 2.0×10^{13}
19. a. $m = 2, n = 3, 4, 5, 6$ b. 397.1 nm
21. 121.6 nm, 102.6 nm, 97.3 nm, 95.0 nm
23. a. 9394°C b. 694°C
25. 2.42 μm
27. a. $0.999998c$ b. $0.99999997c$
29. a. 0.00512 MeV b. 9.39 MeV c. 3.6 MeV
31. 8.4°
33. 9.58×10^7 C/kg, proton
35. a. 0.140 nm b. 1.34×10^6 m/s
37. a. $\lambda = (125.00\text{ nm})/n^2$, $n = 1, 2, 3, \ldots$
b. $\lambda = (75.00\text{ nm})(n^2 - 4)$, $n = 3, 4, 5, \ldots$
39. b. Decreases slightly c. Number of neutrons increases more rapidly than Z
41. Aluminum
43. a. 2.3×10^7 m/s b. 2.9 MeV
45. 13.1 MeV
47. c. $r = 5.29 \times 10^{-11}$ m, $v = 2.19 \times 10^6$ m/s
49. a. 0.295 nm b. -2.44 eV

Chapter 39

1. 6.25×10^{13} electrons/s
3. 3.20 eV
5. 1.78 eV
7. a. Aluminum b. 1.93 V
9. a. 4140 nm; infrared b. 414 nm; visible c. 41.4 nm; ultraviolet
11. a. 1.5×10^{29} b. Wave
13. a. 5.0×10^{14} Hz b. 1×10^{19} photons/s
15. 6.0×10^{-6} V
17. 6
19. 0.427 nm
21. a. Yes b. 0.50 eV
23. $n = 2$: yes; $n = 3$: no
25. a. 31 b. 7.06×10^4 m/s, -0.0142 eV
27. 3.40 eV
31. 97.25 nm
33.

n	r_n (nm)	v_n (m/s)	E_n (eV)
1	0.026	4.38×10^6	-54.4
2	0.106	2.19×10^6	-13.6
3	0.238	1.46×10^6	-6.0

35. a. 1.7×10^{18} photons b. 1.7×10^{26} photons/s

37.

	Potassium	Gold
a. f_0 (Hz)	5.56×10^{14}	1.23×10^{15}
b. λ_0 (nm)	540	244
c. v_{max} (m/s)	10.8×10^5	4.4×10^5
d. V_{stop} (V)	3.35	0.55

39. Sodium

41. a. 0.24 μA

43. a. $E = p/c$ b. $\lambda = h/p$ c. $\lambda = h/mv$

45. a. 2.1×10^{-4} eV b. 2.0 nm c. 3.5 m

47. 0.35 nm

49. 18 fm

51. a. 6.5 eV b. 276 nm, 355 nm c. Both ultraviolet d. 6.16×10^5 m/s

53. -0.278 nm

55. 1282 nm

57. a. $r_{99} = 518$ nm, $v_{99} = 2.21 \times 10^4$ m/s, $r_{100} = 529$ nm, $v_{100} = 2.19 \times 10^4$ m/s
b. $f_{99} = 6.79 \times 10^9$ Hz, $f_{100} = 6.59 \times 10^9$ Hz c. 6.68×10^9 Hz
d. 0.15%

59. $3 \rightarrow 2$: 10.28 nm, $4 \rightarrow 2$: 7.62 nm, $5 \rightarrow 2$: 6.80 nm; all ultraviolet

61. a. 2.06×10^6 m/s b. 12.09 V

63. 4.16 eV

65. a. 1.52×10^{-16} s b. 1.32×10^6

67. a. $r_1 = 4.26 \times 10^{-5}$ nm, $v_1 = 1.31 \times 10^7$ m/s b. 0.0164 nm
c. x ray d. 7.3×10^{13}; yes

Chapter 40

1. $P_C = 20\%$, $P_D = 10\%$

3. a. 7.7% b. 25%

5. a. 1/6 b. 1/6 c. 5/18

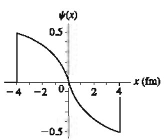
7. 100 V/m

9. $4.0\ \mathrm{m}^{-1}$

11. a. 3333 b. 1111

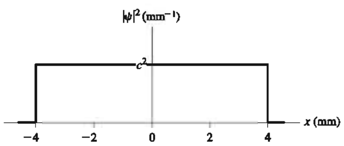
13. a. 5.0×10^{-3} b. 2.5×10^{-3} c. 0 d. 2.5×10^{-3}

15. a. $1/4\ \mathrm{mm}^{-1}$
b.



c. 0.75

17. a. $0.354\ \mathrm{mm}^{-1/2}$
b.



c. 0.25

19. 25 ns

21. 1.0×10^5

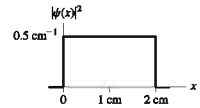
23. -0.65×10^{-36} m/s $< v <$ 0.65×10^{-36} m/s

25. 0 to 2.5×10^7 m/s

27. 9.5 GHz $< f <$ 10.5 GHz

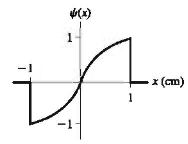
29. 1.0×10^5 pulses/s

31. a.



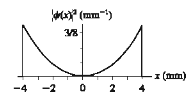
b. 1% c. 10^4 d. $0.5\ \mathrm{cm}^{-1}$

33. a. Yes
b.



c. 0.000, 0.0005, 0.0010 d. 900

35. $\sqrt{3/8}\ \mathrm{mm}^{-1/2}$
b.

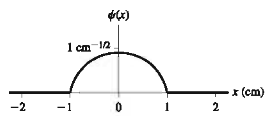


c.

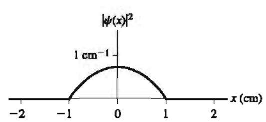
d. 0.125

37. a. 0.27% b. 31.8%

39. a. $0.866\ \mathrm{cm}^{-1/2}$
b.

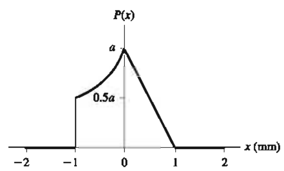


c.



d. 3440

41. a. $a = b$
b.



c. $a = b = 0.838$ d. 58.1%

43. 18 μm

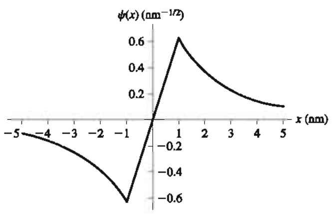
45. a. $0 < v < 4.3 \times 10^{-6}$ m/s b. 4×10^{-15} K

47. a. $\Delta E \Delta t \approx h$ b. The energy of a photon cannot be exactly known.
c. 4.14×10^{-7} eV d. 1.7×10^{-7}

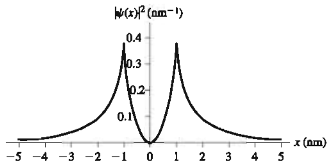
49. 50%

51. a. $\sqrt{3/8}$

b.



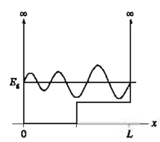
c.



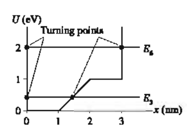
d. 2.5×10^5

Chapter 41

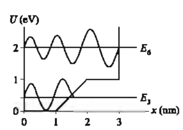
1. 0.739 nm
3. 0.75 nm
7. 0.135
9. 0.038 eV
11.



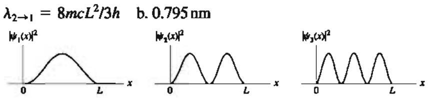
13. a.



b.



15. 150 nm
17. 2.25 N/m
19. 1.35 N/m
21. a. 4.95 eV b. 4.80 eV c. 4.55 eV
25. a. $\lambda_{2\to 1} = 8mcL^2/3h$ b. 0.795 nm
29. a.



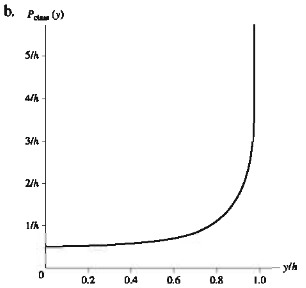
$n =$	1	2	3
b. Most likely	$\frac{1}{2}L$	$\frac{1}{4}L, \frac{3}{4}L$	$\frac{1}{6}L, \frac{3}{6}L, \frac{5}{6}L$
c. Least likely	$0, L$	$0, \frac{1}{2}L, L$	$0, \frac{1}{3}L, \frac{2}{3}L, L$
d. Prob in left $\frac{1}{3}$ from graph	$< \frac{1}{3}$	$> \frac{1}{3}$	$\frac{1}{3}$
e. Prob in left $\frac{1}{3}$ calculated	0.195	0.402	0.333

31. 4.77×10^7 m/s
35. a. $A_1 = \dfrac{1}{(\pi b^2)^{1/4}}$ b. $\text{Prob}(x < -b \text{ or } x > b) = \dfrac{2}{\sqrt{\pi b^2}} \int_b^{\infty} e^{-x^2/b^2}\,dx$

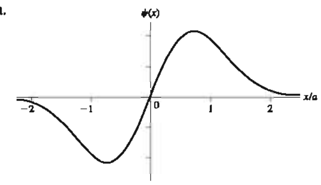
c. 15.7%

37. a. $P_{\text{class}}(x) = \dfrac{1}{2h\sqrt{1 - (y/h)}}$

b.



39. 10^{-463}
43. a.



b. $\pm a/\sqrt{2}$

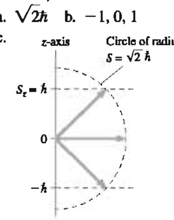
c. $U(x) = \dfrac{2\hbar^2}{ma^2}\left(\left(\dfrac{x}{a}\right)^2 - \dfrac{3}{2}\right)$

45. a. 3.40×10^{-5} b. 2.8 c. 0.005 nm

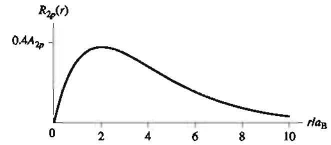
Chapter 42

1. a. $\sqrt{2}\hbar$ b. $\sqrt{12}\hbar$
3. a. f b. -0.85 eV
5. -0.378 eV; $\sqrt{12}\hbar$
7. a. 2 b. 1
9. $1s^22s^22p^63s^23p^3$; $1s^22s^22p^63s^23p^64s^23d^{10}4p^3$; $1s^22s^22p^63s^23p^64s^23d^{10}4p^65s^24d^{10}5p^3$
11. a. Excited state of Ne b. Ground state of Fe
13. $1s^23s^1$
15. a. Yes; 2.21 μm b. No
17. 2.0%
19. b. 9.0×10^5 b. 8.7 ns
21. 3.2×10^{15}
23. a. 1.06 μm b. 1.9 W
25. a. $\sqrt{2}\hbar$ b. $-1, 0, 1$

c.



27. $\sqrt{6}\hbar$
29. a. 3.7×10^{-3} b. 5.4×10^{-3} c. 2.9×10^{-3}
33. a. $R_{2p}(r) = \dfrac{A_{2p}}{2a_B} r e^{-r/2a_B}$



b.
$2a_B$

35. 
37.

a.	Transition	$6s \to 5p$	$6s \to 4p$	$6s \to 3p$
b.	λ(nm)	7290	1630	515

39. 1.13×10^6 m/s
41.

Transition	(a) Wavelength	(b) Type	(c) Absorption
$2p \to 2s$	670 nm	VIS	Yes
$3s \to 2p$	816 nm	IR	No
$3p \to 2s$	324 nm	UV	Yes
$3p \to 3s$	2696 nm	IR	No
$3d \to 2p$	611 nm	VIS	No
$3d \to 3p$	24800 nm	IR	No
$4s \to 2p$	498 nm	VIS	No
$4s \to 3p$	2430 nm	IR	No

43. 
b. 28.7 eV
45. a. $6.25 \times 10^8\ s^{-1}$ b. 0.17 ns
47. 5.7 ns
49. 5.0×10^{16}
51. b. 0.021 nm
53. 8.03%
55. $4.472a_B$
57. a. $p_{atom} = 7.0 \times 10^{-23}$ kg · m/s; $p_{photon} = -8.5 \times 10^{-28}$ kg · m/s
b. 82 400 photons
c. 1.24 ms
d. $-4.05 \times 10^5\ m/s^2$
e. 31 cm

Chapter 43

1.

		Protons	Neutrons
a.	^{3}H	1	2
b.	^{40}Ar	18	22
c.	^{40}Ca	20	20
d.	^{239}Pu	91	145

3. a. 3.8 fm b. 8.2 fm c. 14.5 fm
5. a. $m = 9.988 \times 10^{-27}$ kg; $r = 2.2 \times 10^{-15}$ m;
$\rho = 2.3 \times 10^{17}\ kg/m^3$
b. $m = 3.437 \times 10^{-25}$ kg; $r = 7.1 \times 10^{-15}$ m;
$\rho = 2.3 \times 10^{17}\ kg/m^3$
7. 1.2×10^{11} kg
9. a. ^{36}S and ^{36}Ar b. 5, 8
11. ^{58}Fe: 510 MeV, 8.79 MeV; ^{58}Ni: 506 MeV, 8.73 MeV
13. ^{12}C: 7.68 MeV; ^{13}C: 7.47 MeV; ^{12}C is more tightly bound
15. 20.18 u
17. 8000 N
19. 2.3×10^{-38}
21. a. 
b. ^{14}N is stable; ^{14}C undergoes β^- decay; ^{14}O undergoes β^+ decay
23. a. 9.28×10^{11} b. 4.72×10^{11} c. 5.52×10^8
25. 4.57×10^9
27. 80 d
29. a. ^{228}Th b. ^{207}Tl c. ^{7}Li d. ^{60}Ni
31. ^{228}Th
33. 4.82 MeV
35. 0.225 J
37. 60 mrem
39. a. 3.51×10^7 m/s b. 25.6 MeV
41. a. 12.7 km b. 780 μs
43. a. 1.46×10^{-8} u; 1.45×10^{-6}% b. 0.0304 u; 0.76%
45. 6.0 MeV
47. a. ^{17}N, ^{17}O, ^{17}F b. ^{17}O
c. ^{17}N decays by β^- to ^{17}O; ^{17}F decays by EC to ^{17}O
51. 7.16×10^{11} Bq or 19.4 Ci
53. 2.73×10^{17}
55. a. 19 s b. No
57. 1.2 h
59. 210 million years
61. 70 mrem
63. 3.3×10^{12}
65. a. 2.6×10^{10} b. 0.024 Bq c. 1.4×10^7 rem/yr
d. Yes, ≈ 50 million times background
67. 15 cm
69. ≈ 6 billion years ago
71. a. $K_{in} = 65.0$ MeV; $K_{out} = 5.0$ MeV b. $3.7 \times 10^{21}\ s^{-1}$
c. 6.6×10^{-39} d. 650 million years

Index

For users of the five-volume edition: pages 1–477 are in Volume 1; pages 478–599 are in Volume 2; pages 600–785 for Volume 3; pages 786–1183 for Volume 4; and pages 1140–1365 are in Volume 5. Pages 1184–1365 are not in the Standard Edition.

A

Absolute temperature, 486–87
Absolute zero, 486–87, 548
Absorbed dose, 1354
Absorption
  excitation by, 1317
  of hydrogen, 1231, 1317
  of light, 1224
  of sodium, 1317
Absorption spectra, 1223–24, 1231, 1278, 1317
Accelerating reference frames, 141
Acceleration, 1, 13–17
  angular, 114–16
  average, 13–14, 49, 90–93
  centripetal, 111–12, 387-88
  constant, 48–54, 96–97
  force and, 135-36
  free-fall, 55–56
  Galilean transformation of, 1085–86
  instantaneous, 61–62, 95–96
  nonuniform, 62
  signs of, 18–19
  in simple harmonic motion, 420-21
  tangential, 113
  in two dimensions, 91-92
  in uniform circular motion, 111–13, 212–14
  in uniform electric field, 836
Acceleration constraints, 191–94
Acceleration vectors, 14–15, 81, 214
AC circuits, 1114–32
  AC sources, 1114-17
  capacitor circuits, 1117–19, 1129
  inductor circuits, 1122–23, 1129
  phasors, 1114–17
  power in, 1127–30
  RC filter circuits, 1119–22
  resistor circuits, 1115–17
  series *RLC* circuits, 1124–27
Accommodation, 746
Achromatic doublets, 761
Action at a distance, 805
Action/reaction pair, 184. *See also* Newton's third law of motion
  identifying, 185-88
  massless string approximation and, 196
  propulsion, 188
Activity of radioactive sample, 1347–48
Adiabatic processes, 518, 526–29
Adiabats, 527–28
Agent of force, 127
Air conditioners, 573–74
Air resistance, 54, 132, 162, 169
Airplanes, lift in, 465–66
Allowed transitions, 1317
Alpha decay, 908, 1182, 1349–50, 1350, 1363
Alpha particles, 908, 1194–95, 1196, 1344
Alpha rays, 1193–94, 1334
Alternating current (AC). *See* AC circuits
Ammeters, 977
Amorphous solids, 481
Ampère-Maxwell law, 1094–95, 1096, 1097, 1100–1101
Ampère's law, 1012–16, 1092–94
Amplitude, 411, 419, 609, 621, 638, 639, 659–60, 677
Amplitude function ($A(x)$), 638
Angle of incidence, 703
Angle of reflection, 703
Angle of refraction, 707
Angular acceleration, 114–16, 343, 355, 356
Angular displacement, 108
Angular frequency, 413, 415
Angular magnification, 750
Angular momentum, 373–75, 400–402, 1229–1303, 1334
  conservation of, 372–73
  of hydrogen, 1229, 1300–1303
  of particle, 371
  quantization of, 1229, 1302–3
  of rigid body, 372–75
Angular position, 107–8
Angular resolution, 756
Angular size of object, 749
Angular velocity, 108–10, 225, 343
  angular momentum and, 373–75
Angular velocity vector, 368
Antennas, 1104–5
Antibonding molecular orbital, 1289
Antimatter, 1022, 1175, 1352
Antinodal lines, 655
Antinodes, 636–37, 643, 1272
Antireflection coatings, 651–53
Apertures, 702–3, 743–44, 751
Archimedes' principle, 456
Arc length, 108
Area vectors, 857, 1050
Aristotle, 2, 139
Atmosphere, scale height of, 475
Atmospheric pressure, 447, 452–53
Atomic beam, 1238, 1307
Atomic clock, 24
Atomic mass, 483, 1335–36
Atomic mass number (A), 483
Atomic mass unit (u), 483
Atomic model, 130, 489
Atomic number, 765, 1198, 1309, 1334
Atomic physics, 1300–1328
  electron's spin, 1307–9
  emission spectra, 1230–31, 1318–19
  excited states, 1320–22
  hydrogen atom, 1300–1303
  lasers, 1324–25
  multielectron atoms, 1309–12
  periodic table of elements, 1198, 1223, 1312–16
Atom interferometers, 1218–19
Atoms, 130, 482–85, 489, 715–16, 1184, 1222, 1228–29. *See also* Electrons; Hydrogen; Nuclear physics; Nucleus; Protons
  Bohr model of, 1221–22, 1224–29
  electricity and, 793
  hard-sphere model of, 490
  nuclear model of, 1195, 1197
  plum-pudding or raisin-cake model of, 1194
  properties of, 490
  shell model of, 1306, 1341–43
  structure of, 764–66, 793–94
Avogadro's number, 318, 484

B

Ballistic pendulum, 276
Balmer formula, 1201, 1224–25
Balmer series, 765–66, 1231
Bandwidth, 1251–52
Bar charts, 243–44, 272–73, 322–23
Barometers, 452–56
Basic energy model, 277–78, 302–4
Batteries, 915–16, 922–23, 957–58, 960, 1072–73. *See also* Circuits
  charge escalator model of, 915, 958
  emf of, 915
  ideal, 915
  real, 978–79
  short-circuited, 979
  as source of potential, 914–16
Beam splitter, 688
Beat frequency, 660
Beats, 658–60
Bernoulli, Daniel, 463, 489, 1185
Bernoulli's equation, 462–66, 465
Beta decay, 237, 908, 1207, 1342, 1350–51, 1352, 1362
Beta particles, 908, 1344
Beta rays, 1193–94, 1334
Big Bang, 386, 626
Binding energy, 1228–29, 1338–39
Binoculars, 739

Binomial approximation, 505, 831, 1168
Biot-Savart law, 1003–4, 1088
  and current, 1005–6
Black-body radiation, 532, 1199–1201
Black-body spectra, 1200
Blood pressure, 453–54
Blue shift, 625–26
Bohr, Niels, 1221, 1232, 1275
Bohr model of atomic quantization, 1221–22
  basic assumptions, 1221–22
  quantum jumps, 1222
  stationary states, 1221–22
Bohr model of hydrogen atom, 1224–29
  binding energy, 1228–29
  energy levels, 1227–28
  ionization energy, 1228–29
  quantization of angular momentum, 1229
  stationary states, 1225–26
Bohr radius, 1226–27, 1305
Boiling point, 488, 521
Boltzmann's constant, 493
Bonding molecular orbital, 1289
Boundary conditions
  for standing sound waves, 643–44
  for standing waves on a string, 639–40
  for wave functions, 1266–69
Bound states, 1277–78, 1289
Bound system, 401–2, 1338
Boyle's law, 1185
Bragg condition, 767–69, 772, 781
Brahe, Tycho, 386
Brayton cycle, 578–81, 587–88
Breakdown field strength, 816
Bubble chamber, 1022
Bulk modulus, 468
Bulk properties, 480
Buoyancy, 455–59
Buoyant force, 455

C

Caloric, 515
Calorimetry, 522–23
  with gas and solid, 525
  with phase change, 523
Camera obscura, 702
Cameras, 740–41, 742–45
  exposure, controlling, 743–44
  f-number of lens, 744
  focal length, 744
  pinhole cameras, 699
  shutter speeds, 744
  zoom lenses, 742, 743
Capacitance, 922–27, 931
Capacitive reactance, 1118–19
Capacitors, 922–27. *See also* Parallel-plate capacitors
  charging, 922, 989
  combinations of, 924–27
  dielectric-filled capacitors, 929–31
  discharging, 987–89
  energy stored in, 927–29
  fields inside, 1095
  parallel, 924–25
  particle in, 1286–88
  power in, 1129-30
  series, 925–26
  spherical, 924
Carbon dating, 1348–49
Carnot cycle, 585–88
Carnot engines, 585–88
Carnot thermal efficiency, 588
Cartesian coordinates, 78
Cathode rays, 1187–91
Cathode-ray tube (CRT) devices, 837, 1187
Causal influence, 1171–72

  pressure and, 446
Color, 713–16
  chromatic aberration, 753
  in solids, 1319–20
Compasses, 998, 1000–1001
Component vectors, 79, 80
Compression, 467–68, 497, 512, 616, 642–43
Compression ratio, 596
Compression stroke, 596
Concave mirrors, 728, 730, 731
Condensation point, 488
Conduction
  electrical, 941–44, 1186
  heat, 530–31
  model of, 948–50
Conductivity
  electrical, 954–56
  thermal, 530
Conductors, 792, 795–800
  charge polarization, 798–99
  charging, 796
  dipoles, 799

discharging, 797
in electrostatic equilibrium, 870–72, 921–22
isolated, 796
Conservation laws, 336
Conservation of angular momentum, 372–73
Conservation of charge, 794–95
Conservation of current, 952–53
Conservation of energy, 276–78, 320–25, 337
in capacitors, 884–85
in charge interactions, 892
in fluid flow, 462
Kirchhoff's loop law, 969–72
in motional emf, 1043–48
relativity and, 1176
in simple harmonic motion (SHM), 419
in thermodynamics, 507–8, 516
Conservation of mass, 239
Conservation of mechanical energy, 277–79
Conservation of momentum, 247–53, 1169–72
Conservative forces, 314–16
Constant-pressure (isobaric) process, 496
Constant-temperature (isothermal) compression, 497–98
Constant-volume gas thermometer, 486, 495
Constant-volume (isochoric) process, 495, 524-26, 556
Constructive interference, 637, 648–49, 652–53, 653–55, 682
Contact forces, 127-32
Continuity, equation of, 460–61
Continuous spectrum, 764, 1199–1201
Contour maps, 657–58, 894
Convection, 530–3`
Converging lenses, 716–17
Convex mirrors, 728–29
Coordinate systems, 78–82
Cartesian, 78
displacement and, 8–9
inertial reference frame 141-42
origin of, 6
with tilted axes, 85
Copernicus, Nicholas, 386, 477
Corpuscles, 671
Correspondence principle, 1274–76
Coulomb electric fields, 1059
Coulomb's law, 800–805, 1087–88
Gauss's law vs. 850, 861–62, 865
Couples, 354–55
Covalent bonds, 1288–89
Critical angle, 363, 710
Critical point, 489
Crookes tubes, 1187–88
Crossed-field experiment, 1189–91
Crossed polarizers, 1106
Crossover frequency, 1121
Cross product, 368–71, 1004–5
Crystal lattice, 1299
Crystals, 481, 599, 767–69, 1335
Current, 795, 941–61. *See also* Circuits; Electron current; Induced currents
batteries and, 957–58
conservation of, 952–53
creating, 945–50
displacement, 1092–94
eddy currents, 1047–48
magnetic field of, 1005–9
magnetic force on wires carrying, 1024–26
and magnetism, 1000–1001
root-mean-square current, 1127–28
Current density, 950–54
Current loops, 1007–8
forces and torques on, 1026–28
as magnetic dipole, 1009–12
magnetic field of, 1007–8
Curve of binding energy, 1339
Cyclotron frequency, 1020–21
Cyclotron motion, 1019–21
Cyclotrons, 1022
Cylindrical symmetry, 851–53

D

Damped oscillations, 428–31
Damping constant, 428–31
Daughter nucleus, 1349–50
Davisson-Germer experiment, 772
DC circuits, 967–987
De Broglie, Louis-Victor, 772–73, 1217–18
De Broglie wavelength, 772–74, 1218, 1225–26, 1281–83
Schrödinger's equation and, 1263–65
Decay. *See also* Radioactivity

dipoles in, 839–40
electric potential energy and, 883–85
Uniform magnetic fields, 1015–17
Uniform motion, 34–38. *See also* Uniform circular motion
Units, 24–28
Unit vectors, 82–83
electric fields, unit vector notation for, 809–10
Unit volume, 444
Universal constant, 393
Universal gas constant, 491–92
Unstable equilibrium, 291
Upright images, 720

V

Vacuum, 142
perfect, 447
Valence electrons, 795, 1316
Van Allen radiation belt, 1021
Van de Graaff generators, 914–15
Vapor pressure, 446
Vector algebra, 82–85
addition, 8, 74–76, 83–84
subtraction, 9, 77–78, 84–85
tilted axes of coordinate system and, 85
unit vectors, 82–83
Vector product, 368
Vector quantity, 7, 72
Vectors, 7–11, 72–86. *See also* Vector algebra
area, 857, 1050
components of, 79–82
component, 79, 80
coordinate description of, 78–82
cross product of, 368–70, 1005
decomposition of, 79
displacement, 7–10, 73–74
dot product of, 310–12
graphical addition, 74–75
magnitude of, 73
multiplication by scalar, 76–77
position, 6
properties of, 73–78
resultant, 74
unit, 82–83
zero, 9, 77
Velocity, 11–13. *See also* Acceleration; Angular velocity
acceleration and, 49, 61
average, 11–12, 35, 40, 93–94
Galilean transformation of, 105–6, 287–88, 1085–86, 1145
instantaneous, 38–44, 94
Lorentz transformation of, 1168–69
momentum and, 1171–72
position from, 44–48
relative, 104–7
root-mean-square (rms) speed, 545–49
signs of, 18–19
in two dimensions, 93–96
in uniform circular motion, 111–13, 212–14
Velocity selectors, 542
Velocity vectors, 12–13, 93–94, 213
Venturi tubes, 465–66
Vibrational energy levels, 1285–86
Vibrational transitions, 1286
Virial theorem, 1207
Virtual images, 705, 718, 720–21, 728–29
Viscosity, 459, 1207
Visible spectrum, 618, 714, 765–66
Vision, 745–49
defects in, 746–49

Voltage, 891
Hall, 1023–24
of battery, 915, 978
of capacitor, 923
of inductor, 1066
peak, 1116
of resistor, 957
rms, 1128
terminal, 916, 978–79
Voltmeters, 982–83
Volume, 443–44
flow rate, 461
ideal-gas processes, 495
unit volume, 444
Volume strain, 468
Volume stress, 468. *See also* Pressure

W

Waste heat, 570
Watt, 325–26
Wave fronts, 614, 681
Wave function, 1141, 1239, 1245–46
boundary conditions, 1268–69
drawing, 1282–83
energy and, 1268–71
of hydrogen atom, 1304–7
normalization of, 1247–49, 1271
particle in rigid box, 1268–74
quantum harmonic oscillator, 1283–86
radial wave functions, 1304–7
Schrödinger's equation, 1262–65
shapes of, 1281–83
Wavelengths. *See also* De Broglie wavelengths
Doppler effect and, 623–26
of electromagnetic waves, 618
light wavelength, measuring, 676
of sinusoidal waves, 609, 614
of sound waves, 617
of standing waves, 640
Wave model of light, 602–5, 671–72, 686–87, 1243–44
Wave number, 611
Wave optics, 670–92. *See also* Light
circular-aperture diffraction, 684–87
diffraction grating, 678–81
holography, 690–91
interference of light, 672–78
single-slit diffraction, 681–84
Wave packets, 1216, 1249–53
bandwidth of, 1251–52
uncertainty and, 1252–55
Wave-particle duality, 601, 1208
Waves, 601. *See also* Electromagnetic waves; Light waves; Matter waves; One-dimensional waves; Sinusoidal waves; Sound waves; Standing waves; Traveling waves
circular, 614
disturbance of, 604
Doppler effect, 623–26
intensity of, 620–22
longitudinal, 603, 607
medium of, 603–5
modulation of, 659–60
phase of, 615–16
plane, 614–15
power of, 620–22
shear, 616
speed, 604–5
transverse, 603
two- and three-dimensional waves, 614–16
types of, 603
Weak force, 237
Weight, 160–62
gravitational force and, 389–90
mass compared, 160
Weightlessness, 162, 221
Wien's law, 1200–1201
Wires
current-carrying, 946–47
current density in, 951–52
establishing electric field in, 946–47
Gauss's law and, 868–69
ground, 986
ideal, 959
long-charged wire, electric field of, 868
magnetic field of, 1006–7
magnetic force on, 1024–26
Work, 302–37. *See also* Power
calculating and using, 307–12
in Carnot cycle, 585
by constant force, 307–9
displacement and, 313–14
dot production, calculation with, 311–12
heat and, 514, 567–69
by heat engine, 570
in ideal-gas processes, 509–13
and kinetic energy, 304–6
perpendicular force and, 309–10
and potential energy, 316
by system, 567
by variable force, 312–13
Work function, 1210, 1214
Work-kinetic energy theorem, 306, 507

X

x-axis, 6
x-component of vector, 79
X ray diffraction, 766–69
X ray monochromator, 769
X rays, 767
electrons and, 774–75
ionization by, 1188–89
medical x rays, 1355

Y

y-axis, 6
y-component of vector, 79
Young, Thomas, 671, 714, 1186
Young's double-slit experiment, 672–78, 1186, 1365
Young's modulus, 466–68

Z

Zero
absolute zero of temperature, 486–87
of potential energy, 273–74, 887–88
Zero-point motion, 1273–74
Zero vector, 9, 77
Zoom lenses, 742, 743
